11

12 **Abstract**

13

14 Elevated levels of tropical tropospheric ozone (O<sub>3</sub>) and carbon monoxide (CO), and decreased  
15 water (H<sub>2</sub>O) vapor were observed by the Tropospheric Emission Spectrometer (TES) in the  
16 region of Indonesia and the eastern Indian Ocean during the coincident positive phases of the El  
17 Niño Southern Oscillation (ENSO) and Indian Ocean Dipole (IOD) in late 2006. Using the  
18 chemical transport model GEOS-Chem, we show that the elevated CO results from increased  
19 biomass burning in Indonesia during the ENSO/IOD-induced drought, and quantify the effect of  
20 the fires and other factors on O<sub>3</sub>. In the region of highest CO (~200 ppb), the contribution of the  
21 fires to enhanced O<sub>3</sub> is ~45% in October, ~75% in early November, and only 10% in December.  
22 More lightning in late 2006 compared to 2005 causes an increase in O<sub>3</sub> of a few ppb. Dynamical  
23 changes increase O<sub>3</sub> over a larger region than fire emissions which mainly increase O<sub>3</sub> at 10°N-  
24 10°S in October and November. The model matches the O<sub>3</sub> anomaly in October, but  
25 underestimates it in November and December, which we ascribe to overly active convection in  
26 the model in late 2006, based on an analysis of Outgoing Longwave Radiation (OLR) data. An  
27 underestimate of NO<sub>x</sub> emissions from soils may also contribute to the disparity at the end of the  
28 year. A dramatic decrease in O<sub>3</sub> in late 2006 in equatorial Africa and the western Indian Ocean  
29 is reproduced by the model and is caused by highly enhanced convection in 2006, likely  
30 associated with the IOD.

31

## 1. Introduction

The El Niño Southern Oscillation (ENSO) is a coupled oceanic-atmospheric mode of interannual variability in the Earth system. During the positive phase of ENSO, known as El Niño, sea surface temperatures (SSTs) in the equatorial central Pacific Ocean are persistently higher than normal and are accompanied by changes in ocean currents and surface winds. These changes increase atmospheric convection and humidity over the western Pacific with a corresponding decrease over Indonesia, its neighboring islands and the eastern Pacific [Bjerknes, 1969; Rasmusson and Wallace, 1983]. Through this shift in convection, ENSO affects precipitation, which leads to changes in soil moisture, vegetation growth rates, and the distribution and rate of biomass burning. The impact of El Niño is especially strong for coastal areas of the tropical western Pacific, with the most severe effects experienced in Indonesia, which can lead to large scale changes in the chemical composition of the atmosphere.

An intercomparison of climate models suggests that contemporary El Niño conditions in the tropics may provide an example of the anthropogenically-induced climate warming that will occur in the future [Yamaguchi and Noda, 2006]. Other studies show a strong link between ENSO and the highly variable rate of tropospheric carbon dioxide (CO<sub>2</sub>) accumulation [Bacastow, 1976; Keeling et al., 1995; 2001; Heimann and Reichstein, 2008], with some suggesting that a key mechanism for this variability is the enormous release of CO<sub>2</sub> due to biomass burning that occurs in Indonesia during El Niño [Langenfelts et al., 2002; Page et al., 2002].

The effects of ENSO on atmospheric chemistry, and tropospheric O<sub>3</sub> in particular, have been investigated using both measurements and models. The earliest work used tropospheric O<sub>3</sub> columns derived from satellite observations [Ziemke and Chandra, 1998; Chandra et al., 1998]. These studies analyzed anomalies of O<sub>3</sub>, H<sub>2</sub>O vapor and Outgoing Longwave Radiation (OLR) for the strong 1997 El Niño (computed as the difference between these parameters in the El Niño year and a baseline year) and found that high O<sub>3</sub> over Indonesia correlated with low H<sub>2</sub>O vapor and low convection, while low O<sub>3</sub> over the Pacific correlated with high H<sub>2</sub>O vapor and high convection. The spatial patterns of change in O<sub>3</sub>, H<sub>2</sub>O and OLR are referred to as ‘asymmetric dipole anomalies’. Enhanced O<sub>3</sub> during El Niño was also evident in ozonesonde profiles from Indonesia [Fujiwara et al., 1999; Kita et al., 2000]. Early modeling studies of the tropospheric chemistry associated with ENSO [Hauglustaine et al., 1999; Sudo and Takahashi, 2001; Chandra et al., 2002] along with an observation-based study [Thompson et al., 2001] all concluded that enhanced tropospheric O<sub>3</sub> during the 1997 El Niño was caused by a combination of biomass burning and tropospheric dynamics. Duncan et al. [2003a] investigated the impact of the 1997 Indonesian wildfires on atmospheric composition using the GEOS-Chem model, as well as the contribution to O<sub>3</sub> from NO<sub>x</sub> produced by lightning.

The ENSO-induced drought which occurs on the islands of Indonesia makes this region globally unique in terms of the extreme degree of interannual variability in biomass burning [Duncan et al., 2003b]. While the burning of above-ground vegetation makes a significant contribution to emissions from Indonesia, a larger contribution comes from burning of the thick layer of peat comprising the forest floor [Levine, 1999]. Although most biomass burning is the deliberate result of human activity (primarily to clear land for agriculture), high levels of burning are only

78 possible during periods of prolonged drought, thus natural drivers of tropospheric chemical  
79 variability in the region are difficult to separate from human influence. The level of biomass  
80 burning in Indonesia during the 1997 El Niño was the most extreme for that region ever recorded  
81 [Duncan *et al.*, 2003b], in part because the *Mega Rice Project* promoted by the Indonesian  
82 government from 1995-1999 involved drainage of large areas of peatlands in an unsuccessful  
83 attempt to introduce intense rice farming to southern Kalimantan on the island of Borneo [Page  
84 *et al.*, 2002; Aldhous *et al.*, 2004]. Without this large-scale unsustainable land use prior to the  
85 1997 drought, the degree of burning at the time would likely not have been as severe, although  
86 Field and Shen [2008] showed that the probability of extreme biomass burning in Indonesia is  
87 not represented by a gradual change, but abruptly increases when precipitation drops below a  
88 threshold value.

89  
90 In autumn 2006, the western and central tropical Pacific just north of the equator were wetter  
91 than normal, while Indonesia was much drier [van der Werf *et al.*, 2008], which is consistent  
92 with past El Niño conditions [Chandra *et al.*, 1998; 2007]. The positive phase of the Indian  
93 Ocean Dipole (IOD) [Saji *et al.*, 1999] also correlates with drought in areas surrounding the  
94 Indian Ocean. Although ENSO's impact on Indonesian precipitation is larger than that of the  
95 IOD, Indonesian drought and biomass burning are possibly most intense when the positive  
96 phases of ENSO and IOD coincide, which has only occurred 4 times in the past 50 years,  
97 including autumn 1997 [Saji *et al.*, 1999; Thompson *et al.*, 2001] and 2006 [Field and Shen,  
98 2008]. The second highest level of CO emission from Indonesia reported in biomass burning  
99 inventories occurred in 2006 [van der Werf *et al.*, 2008], surpassed only by 1997. Satellite  
100 observations of tropospheric CO are not available for 1997, but observations in 2006 by multiple  
101 instruments [Logan *et al.*, 2008; Rinsland *et al.*, 2008; Yurganov *et al.*, 2008; also  
102 <http://web.eos.ucar.edu/mopitt/>] show the highest level of tropospheric CO in the satellite record  
103 for this region.

104  
105 In the present work, we investigate tropospheric CO, O<sub>3</sub>, and H<sub>2</sub>O based on observations by the  
106 Tropospheric Emission Spectrometer (TES) [Beer, 2006] during the El Niño and positive IOD in  
107 late 2006, by contrasting to 2005, which was a neutral year with respect to ENSO. TES  
108 observations have sufficient vertical resolution, spatial and temporal coverage, accuracy and  
109 precision for detailed studies of tropospheric chemistry and transport. These simultaneous  
110 coincident measurement of CO, O<sub>3</sub>, and H<sub>2</sub>O from TES provide an advantage relative to many  
111 earlier studies of O<sub>3</sub> during El Niño, since CO is a more direct proxy for biomass burning than  
112 aerosols, which were used in the past [Thompson *et al.*, 2001; Chandra *et al.*, 2002]. Logan *et al.*  
113 [2008] identified strong anomalies in TES CO, O<sub>3</sub>, and H<sub>2</sub>O during October and November of  
114 2006. Using TES observations and the GEOS-Chem model [Bey *et al.*, 2001], we investigate the  
115 effects of biomass burning emissions, lightning and convection on tropospheric CO, O<sub>3</sub> and H<sub>2</sub>O  
116 levels over Indonesia and its surroundings during late 2006.

## 117 118 **2. Description of Observations and Model Runs**

### 119 **2.1 TES Measurements**

120  
121 TES is a Fourier transform spectrometer that measures infrared emission of Earth's atmosphere  
122 with a focus on the troposphere. TES is on the Aura satellite, which has a ~705 km sun-  
123 synchronous near-polar orbit with an equator crossing time of ~13:45 and a 16-day repeat cycle.

124 The primary measurement mode for TES is the Global Survey (GS), during which it makes nadir  
125 observations with a  $5.3 \times 8.3 \text{ km}^2$  footprint, surveying the earth in 16 orbits (~26 hours).  
126 Measurements from subsequent TES orbit tracks in a GS are offset by  $22^\circ$  longitude such that  
127 near global coverage is obtained after one repeat cycle of 8 GS or approximately 16 days.

128  
129 TES retrievals are based on the optimal estimation approach [Rodgers, 2000] and are described  
130 in Worden *et al.* [2004] and Bowman *et al.* [2002; 2006], with error characterization described in  
131 Kulawik *et al.* [2006]. Temperature, water vapor and  $\text{O}_3$  are simultaneously retrieved in the first  
132 step of the retrieval with other species and parameters retrieved in subsequent steps. In version 2  
133 (v02 or F03\_03), TES retrieved profiles are provided on a 67-level vertical grid from the surface  
134 to 0.1 hPa.

135  
136 Validation of TES V002  $\text{O}_3$  retrievals using ~1600 coincidences with ozonesondes by Nassar *et al.*  
137 [2008] indicated a high bias of 3-10 ppb with variation related to latitude zone and season.  
138 Similar results were found by Richards *et al.* [2008] using aircraft lidar measurements.  
139 Comparisons of TES V002 CO and Measurement of Pollution in the Troposphere (MOPITT) CO  
140 indicated consistency between the datasets [Luo *et al.*, 2007a], while comparisons of TES CO  
141 with in situ aircraft measurements showed agreement within  $\pm 15\%$  [Luo *et al.* 2007b; Lopez *et al.*,  
142 2008]. TES V003  $\text{H}_2\text{O}$  vapor profiles were found to be ~5% high in the lower troposphere  
143 and up to ~15% high in the upper troposphere relative to Vaisala radiosonde measurements  
144 [Shephard *et al.* 2008]. This is believed to be slightly better than V002  $\text{H}_2\text{O}$  used in the present  
145 work.

146  
147 In cloud-free conditions, TES nadir  $\text{O}_3$  profiles typically have nearly two degrees of freedom for  
148 signal (DOFS) in the tropical troposphere [Bowman *et al.*, 2002; 2006; Worden *et al.*, 2004;  
149 Worden *et al.*, 2007], and thus can be thought of as containing independent information on upper  
150 tropospheric and lower tropospheric  $\text{O}_3$ . The strength of the TES CO signal has varied over  
151 time, primarily as a result of instrument sensitivity. From 29 November 2005 to 2 December  
152 2005, the TES optical bench was warmed to remove the build-up of contaminants on instrument  
153 optics. This procedure improves the measured signal, primarily impacting the spectral  
154 frequencies of the CO retrievals. Prior to decontamination, CO typically had 0.7-0.8 DOFS but  
155 following the procedure, CO has 1.4-1.5 DOFS in the troposphere [Rinsland *et al.*, 2006]. TES  
156 water vapor profiles typically have 3-5 DOFS (or a vertical resolution of ~3.5 km), nearly all of  
157 which correspond to the troposphere since air above the tropopause is comparatively dry  
158 [Shephard *et al.*, 2008].

159  
160 All TES  $\text{O}_3$ , CO and  $\text{H}_2\text{O}$  data used in this work were screened to remove cloudy profiles  
161 (defined as having an effective optical depth greater than 2.0 and cloud top height above 750  
162 hPa) and other potentially erroneous profiles using the recommended TES data quality flags.  
163 Ozone underwent additional screening based on the emission layer flag [Nassar *et al.*, 2008].  
164 Upper tropospheric  $\text{H}_2\text{O}$  had additional filtering applied to prevent erroneous extreme high  
165 outliers from skewing the average VMR, by rejecting points with a VMR greater than 10 parts  
166 per thousand (ppth) above 510 hPa.

167  
168 The optimal estimation approach used in TES retrievals combines information from a  
169 measurement with a priori knowledge of a given quantity to produce an estimate with greater

170 precision than either the measurement or a priori has independently. However, the accuracy of  
171 this estimate only improves if the a priori used does not introduce a bias. TES O<sub>3</sub> and CO a  
172 priori distributions vary by month (both vertically and horizontally) and come from averaged  
173 MOZART model runs [Brasseur *et al.*, 1998], while TES V002 monthly H<sub>2</sub>O a priori  
174 distributions come from averaged GEOS-4 analyses. To avoid introducing biases, we apply  
175 uniform a priori profiles (calculated by averaging the July prior for a given species for 30°S-  
176 30°N) to all TES O<sub>3</sub>, CO and H<sub>2</sub>O data so that any spatial variation comes exclusively from the  
177 measurements. A uniform a priori has been applied to TES data in several other studies [i.e.  
178 Zhang *et al.*, 2006; Luo *et al.*, 2007a; Logan *et al.*, 2008] with the procedure and implications  
179 discussed in Kulawik *et al.* [2008].

180

## 181 2.2 GEOS-Chem

182

183 Model simulations were carried out using the chemical transport model GEOS-Chem [Bey *et al.*,  
184 2001], which uses assimilated meteorology from the Goddard Earth Observing System version 4  
185 (GEOS-4). Unless otherwise stated, model runs were based on a modified model version 7-04-  
186 10, in which the method used to constrain the lightning spatial distribution was improved as  
187 described below. This modification has since been incorporated into the standard GEOS-Chem  
188 code as of v7-04-12. Updated descriptions of the O<sub>3</sub>-NO<sub>x</sub>-hydrocarbon-aerosol simulation can  
189 be found in Park *et al.* [2006] and Hudman *et al.* [2007]. Modifications implemented to the  
190 standard biomass burning module are also described below.

191

192 The simulations used the EDGAR fossil fuel inventories for CO, NO<sub>x</sub> and SO<sub>2</sub> for the year 2000  
193 [Olivier and Berdowski, 2001] (scaled forward to 2002), implemented in GEOS-Chem by van  
194 Donkelaar *et al.* [2008]. These were overwritten with the following regional inventories: the Co-  
195 operative Programme for Monitoring and Evaluation of the Long-range Transmission of Air  
196 Pollutants in Europe (EMEP) inventory for Europe in 2000 [Vestreng and Klein, 2002], the  
197 Environmental Protection Agency's National Emission Inventory 1999 (EPA-NEI-99) for the  
198 U.S., the Big Bend Regional Aerosol and Visibility Observational (BRAVO) Study Emissions  
199 Inventory for Mexico in 1999 [Kuhns *et al.*, 2003], and the inventories of Streets *et al.* [2003] for  
200 Asia in 2000 and of Streets *et al.* [2006] for CO from China in 2001. Anthropogenic hydrocarbon  
201 emissions are described in Bey *et al.* [2001] and were scaled forward to 1998.

202

203 Biogenic emissions are based on the Model of Emissions of Gases and Aerosols from Nature  
204 (MEGAN) [Guenther *et al.*, 2006] which computes emissions for plant functional types as a  
205 function of temperature, solar radiation, leaf area index and leaf age. Biofuel emissions are from  
206 the generic annual inventory of Yevich and Logan [2003]. Biomass burning emissions are from  
207 the Global Fire Emission Database version 2 (GFEDv2 or simply GFED below) [van der Werf *et*  
208 *al.*, 2006] which uses Moderate Resolution Imaging Spectroradiometer (MODIS) fire counts  
209 [Giglio *et al.*, 2006] to determine the locations and times of active biomass burning areas.  
210 Emission of CO and other combustion by-products in GFED are calculated based on emission  
211 factors for each species and for three vegetation types (savanna, tropical forest and temperate  
212 forest). For this work we implemented the 8-day GFED emissions in GEOS-Chem. These were  
213 derived by resampling the inventory to 8 day means using MODIS fire hot spots [Giglio *et al.*,  
214 2003; [www.ess.uci.edu/~jranders/](http://www.ess.uci.edu/~jranders/)].

215

216 In earlier versions of GEOS-Chem, the spatial distribution of NO<sub>x</sub> emissions from lightning was  
217 determined directly from cloud top heights (CTHs) in the GEOS meteorological fields. The  
218 parameterization based on *Price and Rind* [1992] calculated flash densities as a power-function  
219 of convective CTHs with vertical profiles of NO<sub>x</sub> from *Pickering et al.* [1998], as implemented  
220 in *Wang et al.* [1998]. Knowledge of the global lightning distribution has since been greatly  
221 improved by the combined climatological product of the Optical Transient Detector (OTD) on  
222 the Micro-Lab 1 satellite, which measured lightning flashes from a near-polar orbit with a 70°  
223 inclination from April 1995 to March 2000 [*Christian et al.*, 1996; 2003; *Mach et al.*, 2007], and  
224 from the Lightning Imaging Sensor (LIS) [*Christian et al.*, 1992; *Mach et al.*, 2007] on the  
225 Tropical Rainfall Measuring Mission (TRMM) satellite which has been making lightning flash  
226 observations since December 1997 from ~35°N to ~35°S.

227  
228 The cloud top height scheme gives the overall best simulation of the global lightning distribution  
229 within the GEOS-4 meteorological framework, relative to others in the literature. However, it  
230 fails to capture relative magnitudes between the predominant large-scale lightning features, and  
231 its separate equations for marine and continental boxes do not simulate well the local lightning  
232 patterns over the Maritime Continent. Various techniques have been used to constrain the GEOS-  
233 Chem distribution of lightning to match the satellite observations. *Stajner et al.* [2008] and  
234 *Jourdain et al.* [2008] adopted a regional approach, while *Sauvage et al.* [2007a] matched the  
235 model lightning at the grid-box level. In our approach, the model spatial distribution of lightning  
236 averaged over 11 years is constrained to match the 11-year High Resolution Monthly  
237 Climatology (HRMC v2.2) combined product of LIS/OTD (available from NASA's Global  
238 Hydrology and Climate Center GHCC), performed via monthly scaling factors applied at the  
239 model grid resolution. This approach is similar to the method of *Sauvage et al.* [2007a], but they  
240 used an earlier LIS/OTD product with coarser spatial and temporal smoothing, and constrained  
241 only with seasonal scale factors. Lightning NO<sub>x</sub> injection heights follow the vertical distribution  
242 functions of *Pickering et al.* [1998], scaled to cloud top height and approximately 6 Tg N a<sup>-1</sup> are  
243 released globally. The lightning parameterization used here is described in detail in *Murray et al.*  
244 (manuscript in preparation).

245  
246 Initialization of the model consisted of a 9-month spin-up beginning in December 2004, followed  
247 by multiple runs (outlined in Table 1) spanning the 15 month period from September 2005 to  
248 December 2006. Model runs were carried out at the GEOS-4 resolution of 2° latitude by 2.5°  
249 longitude and a 30-level (reduced) vertical grid from the surface to 0.01 hPa. Model time steps  
250 were set to 15 minutes for transport and convection, and 60 minutes for emissions and chemistry.

251  
252 Although the pure O<sub>3</sub> tracer is available in GEOS-Chem, the O<sub>x</sub> tracer is much more commonly  
253 used and is essentially the same as O<sub>3</sub> but includes a contribution from NO<sub>2</sub> (which is only  
254 significant near the surface, close to strong sources) and a contribution from O which is only  
255 significant above the tropopause. Our focus below is on the 825-287 hPa range, which makes  
256 the O<sub>x</sub> or O<sub>3</sub> distinction negligible, so for the remainder of the paper, we only refer to O<sub>3</sub> even if  
257 O<sub>x</sub> was used. Water vapor is provided as a GEOS-4 meteorological field in the form specific  
258 humidity (q) and this quantity is directly converted to H<sub>2</sub>O VMR.

### 260 **2.3 TES and Model Comparison Method**

261

262 To compare TES and model CO, O<sub>3</sub>, and H<sub>2</sub>O, the model was sampled at the position and closest  
263 time of the TES measurements. The CO and O<sub>3</sub> model output had 3-hour resolution while the  
264 GEOS-4 H<sub>2</sub>O consisted of 6-hour averages. All TES profiles for a given model gridbox  
265 (typically 1-2) that correspond to the closest time were averaged. To increase the information  
266 content from TES measurements for all 3 species, we averaged the six TES levels spanning 825-  
267 511 hPa for the lower troposphere (LT) and the six levels spanning 464-287 hPa for the upper  
268 troposphere (UT), approximately corresponding to the tropospheric O<sub>3</sub> DOFS. The model  
269 profiles were interpolated to the TES 67-level vertical grid, accounting for variations in surface  
270 pressure, then transformed using the TES averaging kernel (AK) and a priori profiles to match  
271 the TES vertical resolution. The uniform TES a priori profiles mentioned in the previous section  
272 were also applied to the model results in all comparisons.

273

### 274 3. Results and Analysis

#### 275 3.1 CO, O<sub>3</sub> and H<sub>2</sub>O Distributions in Late 2006

276

277 Figure 1 shows maps of CO, O<sub>3</sub> and H<sub>2</sub>O for October, November and December 2006 for the LT  
278 the TES observations (left), the model *Base* run with the corresponding TES averaging kernels  
279 applied, (herein referred to as GEOS-Chem wAK, center) and the difference (model wAK –  
280 TES, right). In the LT, there is ~1 DOFS for O<sub>3</sub>, <1 for CO and ~2 for H<sub>2</sub>O. In Figure 1 and  
281 many other figures, white pixels indicate an absence of TES observations in those grid boxes.  
282 TES data plotted here are the same as in *Logan et al.* [2008], but here we show a higher  
283 horizontal resolution and average six TES vertical levels rather than using a single level, 511  
284 hPa.

285

286 The TES CO maps show a very strong maximum over Indonesia and the Indian Ocean, which  
287 exceeds 200 ppb in October and November, but essentially disappears in December. Secondary  
288 maxima are also observed over South America, Africa and China. CO spatial distributions from  
289 TES and the model in Figure 1 agree very well in terms of the shapes and locations of these  
290 prominent CO maxima, but model CO is systematically lower than TES. The difference map  
291 shows that this bias is typically less than one division on the color scale (10 ppb). The model is  
292 too low by more than 30 ppb in the regions of Indonesia (particularly November), eastern China  
293 (October only) and southwestern Africa, while the model is slightly high over western South  
294 America. These differences exceed the TES bias of  $\pm 10$  ppb (*Luo et al.*, 2007; *Lopez et al.*,  
295 2008]. Overall, there is very little difference between TES CO in the LT and UT (not shown) due  
296 to the limited DOFS available from TES. In October, separate Indonesian-Indian Ocean and  
297 eastern China CO maxima are resolved, unlike in *Logan et al.* [2008], resulting from the  
298 inclusion of information from lower levels. Very high CO levels in this region were also  
299 observed by the Atmospheric Chemistry Experiment Fourier Transform Spectrometer (ACE-  
300 FTS) [*Rinsland et al.*, 2008] and the Measurement of Pollution in the Troposphere (MOPITT)  
301 instrument (<http://web.eos.ucar.edu/mopitt/>) around the same time.

302

303 Figure 1 shows some similarities between TES and GEOS-Chem O<sub>3</sub>, for example, both show a  
304 minimum in O<sub>3</sub> over the tropical Pacific Ocean and to a lesser extent over the equatorial Indian  
305 Ocean. The highest TES O<sub>3</sub> levels are found in the southern tropics extending west from the east  
306 coast of South America to the northwest coast of Australia and the southern coast of the  
307 Indonesian island of Java. GEOS-Chem O<sub>3</sub> generally agrees well with the spatial patterns seen

308 by TES but is as much as 20-30 ppb lower than TES over portions of the tropical Atlantic and  
309 western Africa in October. The model O<sub>3</sub> is also too low by 10-25 ppb over parts of the eastern  
310 Indian Ocean in November and December. These differences exceed the 1 $\sigma$  high bias of 3-10  
311 ppb identified during TES V002 O<sub>3</sub> validation [Nassar *et al.*, 2008]. The TES and GEOS-Chem  
312 distributions have numerous similarities to the tropospheric O<sub>3</sub> residual distributions determined  
313 from a combination of Ozone Monitoring Instrument (OMI) and Microwave Limb Sounder  
314 (MLS) for the same time period [Chandra *et al.*, 2009]. Figure 2 compares model profiles to  
315 soundings at Java, Kuala Lumpur and Samoa from the Southern Hemisphere Additional  
316 Ozonesonde (SHADOZ) network [Thompson *et al.*, 2003: 2007] in late 2005 and 2006,  
317 indicating excellent overall agreement, with the largest discrepancies in November 2006.

318  
319 Figure 1 shows excellent agreement between TES and GEOS-4 H<sub>2</sub>O, considering the large  
320 variability in tropospheric H<sub>2</sub>O. No obvious bias is revealed, only single scattered grid boxes are  
321 too high or low.

### 322 **3.2 2006-2005 CO, O<sub>3</sub> and H<sub>2</sub>O Anomalies**

323  
324 Figure 3 shows the difference between 2006 and 2005 for the LT in October, November and  
325 December for TES (left) and the GEOS-Chem *Base* run wAK (right); results for the UT are  
326 similar, so are not shown. These differences, which we will refer to as anomalies, remove some  
327 systematic errors such as retrievals biases or any remaining effect of a priori values (although  
328 this has primarily been dealt with by application of a constant prior to TES and the model), and  
329 model biases. Figure 3 shows a very strong positive CO anomaly from TES in the vicinity of  
330 Indonesia in October and November 2006, which is essentially absent in December. A much  
331 weaker negative anomaly is seen over the equatorial eastern Pacific, South America and the  
332 south Atlantic in October that is reduced in November, then shifts to western-equatorial Africa in  
333 December. The positive CO anomaly closely resembles the large CO maximum in Figure 1, but  
334 agreement between TES and the *Base* model anomalies is better, most likely because some  
335 biases cancel.

336  
337 Figure 3 shows a strong positive O<sub>3</sub> anomaly of as much as ~30 ppb over Indonesia and the  
338 eastern Indian Ocean including the Bay of Bengal, which is not evident from Figure 1 since O<sub>3</sub> is  
339 low in this region. The area of elevated O<sub>3</sub> is largest in October 2006 and decreases in extent in  
340 November and December in both the TES measurements and the model. The model matches the  
341 observed anomaly well in October, except in the Bay of Bengal, but underestimates it in  
342 November and December. One notable deficiency in the model is the division of the major  
343 positive anomaly in December due to a weakening of the anomaly over Indonesia (at 10°S-  
344 10°N), which is not seen in the observations. The negative lobe of the El Nino ‘asymmetric  
345 dipole anomaly’ for O<sub>3</sub> as described by Chandra *et al.* [1998; 2007], is observed over the central  
346 Pacific in October and December, but is noticeably absent in November for both TES and the  
347 model. The dipole anomaly is also evident in the sonde data and model comparisons in Figure 2.  
348 Ozone is lower at Java and Kuala Lumpur in October-December 2005 than in 2006, while it is  
349 higher in those months at Samoa in 2005 than in 2006, and the model captures most of these  
350 differences. Both TES and the model also show another negative O<sub>3</sub> anomaly over equatorial  
351 Africa which is strongest in December; this anomaly may be the IOD analogue to the El Niño  
352 Pacific O<sub>3</sub> anomaly.

354  
355 TES and GEOS-4 H<sub>2</sub>O anomalies show excellent agreement. Interestingly, the 10°S-10°N gap in  
356 the December positive O<sub>3</sub> anomaly in Figure 3 coincides with a similar gap in the negative H<sub>2</sub>O  
357 anomalies from both TES and GEOS-4. An inverse relationship can be seen between many of  
358 the H<sub>2</sub>O anomalies and co-located O<sub>3</sub> anomalies of the opposite sign, but upon close inspection,  
359 the largest positive O<sub>3</sub> anomaly in October is not entirely co-located with the strong negative  
360 H<sub>2</sub>O anomaly which is smaller in extent and peaks more to the south. Reasons for similarities  
361 and differences between the CO, O<sub>3</sub> and H<sub>2</sub>O anomalies and between TES and GEOS-Chem are  
362 explored below.

### 363 364 **3.3 The Influence of Biomass Burning Emissions**

365  
366 *Logan et al.* [2008] showed CO anomalies similar to those in Figure 3 and attributed the large  
367 Indonesia and equatorial Indian Ocean anomaly during October and November to severe biomass  
368 burning in Indonesia during the 2006 drought. We ran the model for 2006 using GFED  
369 emissions for the corresponding months in 2005 (designated '2006e05') to quantify the effect of  
370 changes in biomass burning emissions on CO and O<sub>3</sub>. As expected, the large CO anomaly  
371 around Indonesia in October and November essentially disappears (Figure 4) since GFED  
372 emissions of CO from Indonesia were only 5.8 Tg in September to December 2005 compared  
373 with 67.3 Tg for the same period in 2006.

374  
375 Large anomalies for O<sub>3</sub> remain from the 2006e05 simulation. It is striking that the component of  
376 the O<sub>3</sub> anomaly unrelated to biomass burning is coincident with the observed H<sub>2</sub>O anomaly,  
377 while the component of the O<sub>3</sub> anomaly near Indonesia in Figure 3 that is related to biomass  
378 burning is essentially coincident with that for CO (10°N-10°), particularly in October. These  
379 results for 2006 confirm earlier findings denoting contributions to elevated O<sub>3</sub> from both biomass  
380 burning and meteorology during the 1997 El Niño event [*Hauglustaine et al.*, 1999; *Sudo and*  
381 *Takahashi*, 2001; *Thompson et al.*, 2001; *Chandra et al.*, 2002; *Duncan et al.*, 2003a]. However,  
382 our model analysis in combination with TES data allows better delineation of the location of  
383 these effects.

384  
385 Comparisons of CO simulated using 8-day and monthly GFED emissions (not shown) show little  
386 difference for averages of a month or longer, but a significant difference is found when working  
387 with half-month or shorter timescales. To better understand the time evolution of the CO and O<sub>3</sub>  
388 enhancements, we take advantage of the 16-day repeat cycle of TES global surveys and the  
389 GFED 8-day resolution. Figure 5 shows CO for half-month intervals from TES and GEOS-  
390 Chem, with the exact time periods given in Table 2, selected to avoid splitting TES global  
391 surveys.

392  
393 Figure 5 illustrates the dramatic change in the CO maximum in the Indian Ocean between the  
394 first and second half of November in both the observations and the model. The time evolution of  
395 CO, O<sub>3</sub>, and H<sub>2</sub>O averaged over the box region (11°S-5°N and 91.25-121.25°E) corresponding to  
396 peak CO is shown in Figure 6. Averages for the LT and UT are given for O<sub>3</sub> and H<sub>2</sub>O, but only  
397 for the LT for CO as the UT average is very similar. These plots reinforce that the model is  
398 systematically low relative to TES for both CO and O<sub>3</sub>. TES O<sub>3</sub> has a well-established  
399 systematic high bias as noted above. Validation showed that TES O<sub>3</sub> was high by ~3 ppb in the

400 UT and ~9 ppb in the LT in the tropics (15°N-15°S) [Nassar *et al.*, 2008], so these quantities  
401 were subtracted from the TES time-series as a bias correction (Figure 6), reducing the difference  
402 between the base model simulation and TES O<sub>3</sub>. We opted not to apply a bias correction to the  
403 O<sub>3</sub> maps since they span 30°S-30°N, and validation work identified different values of the bias  
404 for the tropics, northern subtropics and southern subtropics [Nassar *et al.*, 2008]. No correction  
405 is applied for either TES CO or H<sub>2</sub>O, as these biases are not as well-characterized.

406  
407 A sharp decrease in model CO is apparent in the first half of November, prior to a decrease in  
408 TES CO. GFED CO biomass burning emissions for the same region are also shown in Figure 6  
409 as half-month averages. Since the time evolution of model CO closely follows that of the GFED  
410 emissions, we evaluate the timing in GFED by comparing with precipitation data. Precipitation  
411 data (<http://www.tutiempo.net/>) is shown in Figure 7 for two sites in southern Borneo near the  
412 2006 fires, Palangkaraya (1°S, 114°E) and Banjarmasin (3.43°S, 114.75°E). Clearly, the high  
413 GFED emissions correspond to the long dry period. The 1.02 mm of rain recorded at  
414 Palangkaraya on October 22 is the only evidence for a reduction in biomass burning emissions  
415 for the October 16-23 period. The onset of rain at Banjarmasin on November 3 and  
416 Palangkaraya on November 6 correspond with the reduction of CO emissions in early November.  
417 Whether or not these small quantities of rain could have such a large effect on CO emissions  
418 from the fires is not clear. In 1997, the vast majority of fire emissions from Borneo were the  
419 result of peat burning [Levine 1999], which tends to smolder after the onset of rain [Khandekar  
420 *et al.*, 2000], and this is likely the case also in 2006. Since GFED determines emissions based on  
421 MODIS fire counts, it only includes actively flaming fires and does not directly account for fires  
422 that are dying out and smoldering, although these likely emit CO with a higher CO/CO<sub>2</sub> ratio for  
423 the same fuel load due to more incomplete combustion. To account for continuing CO emissions  
424 after the onset of rain as a result of smoldering peat, we ran the model with various scaling  
425 factors applied to GFED emissions for November, followed by a return to normal emissions in  
426 December. A scaling factor of 3 best reproduced the shape of the LT and UT CO timeseries  
427 lines (Figure 6) and made a modest improvement to the shape of the O<sub>3</sub> timeseries.

428  
429 The time evolution of O<sub>3</sub> differs between TES and the model in a more complicated way than for  
430 CO, suggesting contributions from multiple factors. The model O<sub>3</sub> matches the time evolution  
431 from TES within a few ppb from early September to early November in the run with increased  
432 November emissions. However, the model O<sub>3</sub> decreases by ~ 9 ppb from early to late November  
433 in the LT (~ 7 ppb in the UT), while TES O<sub>3</sub> increases slightly in the LT, and stays constant in  
434 the UT. Model and observed O<sub>3</sub> decrease thereafter, at about the same rate, but the model is  
435 systematically low by ~ 5 ppb in the LT and ~8 ppb in the UT.

436  
437 We estimate the contribution from Indonesian biomass burning to the O<sub>3</sub> anomaly using the  
438 model run with increased GFED emissions in November, again comparing to the run with 2005  
439 GFED emissions (2006e05). Figure 8 shows the total 2006-2005 O<sub>3</sub> anomalies in each month  
440 (with the TES AK applied), the contribution resulting from enhanced burning in 2006, and the  
441 contribution from other factors. Figure 8 indicates that the O<sub>3</sub> anomaly caused only by enhanced  
442 biomass burning in 2006 (relative to 2005) is located primarily from the equator to 10°S and west  
443 of 120°E in October, while that caused by factors related to dynamics is located primarily at 10°-  
444 20°S and extends east as well as west of 120°E. There is also a disconnect between the locations

445 of the biomass burning related anomaly and the main dynamically related anomaly in November.  
446 The spatial extent of the dynamically related anomalies is larger.

447  
448 Even in the equatorial region however, there is an influence of factors other than biomass  
449 burning on O<sub>3</sub>. This is quantified for the box region by comparing the results for the 2006e05  
450 run (dashed blue line in Figure 6), the run with increased GFED emissions in November in 2006,  
451 and the 2005 Base run. For this box we find that the fires in 2006 accounted for an average of  
452 ~45% of the O<sub>3</sub> anomaly in October, ~75% in early November, ~45% in late November, and  
453 only 10% in December (Table 3).

### 454 455 **3.4 Lightning and its Contribution to O<sub>3</sub>**

456  
457 *Logan et al.* [2008] hypothesized that the persistence of the O<sub>3</sub> anomaly weeks after the large CO  
458 anomaly had disappeared could be related to enhanced lightning NO<sub>x</sub> emissions over Indonesia  
459 and New Guinea, since LIS flash rates in November and December 2006 were as much as 200%  
460 higher than those in 2005 at certain locations on these islands. A comparison of the lightning  
461 flash rates between GEOS-Chem and LIS observations (Figure 9) indicates that the model  
462 significantly underestimates the differences over Indonesia and New Guinea in November and  
463 December of the two years. *Hamid et al.* [2001] showed that during the 1997 El Niño (which  
464 also had a positive IOD), convection over Indonesia was less frequent but more intense than  
465 usual and that there was a significant overall increase in regional lightning activity. Figure 9  
466 demonstrates that the lightning parameterization used here, based on cloud top height in the  
467 GEOS-4 convection scheme and on mean spatial patterns from LIS data, does not capture the  
468 correct interannual variability of lightning. In particular it does not capture the difference  
469 between a neutral ENSO year and one with a coincident El Niño and positive IOD.

470  
471 To quantify the effects of lightning NO<sub>x</sub> on tropospheric O<sub>3</sub> in 2005 and 2006, we ran the model  
472 with these NO<sub>x</sub> emissions turned off (*NoLight*) and the compared results to a baseline run from  
473 the same model version (v7-04-13). Differences (with the TES AK and constant a priori applied)  
474 are shown for October to December of each year in Figure 10. Lightning NO<sub>x</sub> increases O<sub>3</sub>  
475 throughout the tropics with sensitivities peaking in the tropical south Atlantic at ~50-60 ppb in  
476 the UT and ~30-40 ppb in the LT. Near Indonesia and over the Indian Ocean, the sensitivity is  
477 much less, rarely exceeding 10 ppb.

478  
479 Figure 10 also shows the O<sub>3</sub> anomaly for the *NoLight* runs. The monthly anomalies over  
480 Indonesia and the Indian Ocean are very similar to those in Figure 3 for the runs with NO<sub>x</sub> from  
481 lightning, implying a modest contribution of lightning to the anomaly. However, there is a much  
482 smaller negative O<sub>3</sub> anomaly over equatorial Africa in December in the *NoLight* runs compared  
483 to Figure 3, showing a much larger impact of differences in lightning NO<sub>x</sub> between the two years  
484 there.

485  
486 *Duncan et al.* [2003a] used GEOS-Chem with an older lightning parameterization to conduct a  
487 similar sensitivity test for the 1997 El Niño, turning off lighting for September-December. They  
488 found that the global lightning contribution to daily O<sub>3</sub> profiles over Java reached a maximum of  
489 15-25 ppb between 400 and 200 hPa UT, and was much less at lower altitudes. *Sauvage et al.*  
490 [2007b] ran GEOS-Chem, separately applying a 1% decrease to NO<sub>x</sub> emissions from lightning,

491 soils, biomass burning and fossil fuel emissions over all seasons, indicating that O<sub>3</sub> was more  
492 sensitive to the change in lightning NO<sub>x</sub> than to changes in other NO<sub>x</sub> sources, but they did not  
493 evaluate the effects of perturbing emissions of other O<sub>3</sub> precursors such as CO that also result  
494 from biomass burning. The spatial distributions of O<sub>3</sub> enhancements resulting from the lightning  
495 NO<sub>x</sub> in Figure 10 and in *Sauvage et al.* [2007b] show similar features.

496  
497 Since lightning in our baseline model runs produces up to 10 ppb O<sub>3</sub> over Indonesia and the  
498 Indian Ocean, the enhancement of lightning during the positive phase of ENSO and the IOD  
499 could account for a portion of the 2006-2005 anomaly and help to explain the TES-model  
500 discrepancy. We addressed this by scaling the model lightning from October to December 2006  
501 according to flash rate ratios from the LIS Science Data product for 2006:2005. These scale  
502 factors,  $f_{\text{mon}}$ , calculated for land grid boxes in Indonesia and New Guinea (9°N-13°S and 93.75-  
503 151.25°E) were 0.6 for October, 1.4 for November and 2.0 for December. Scaling lightning  
504 reduces O<sub>3</sub> in 2006 up to ~3 ppb in the LT and ~5 ppb in the UT in October, followed by slightly  
505 larger enhancements in November. In December, O<sub>3</sub> is enhanced by ~5 ppb in the LT and by  
506 ~10 ppb in the UT, with the enhancement centered at about 5°S. When these localized changes  
507 are averaged over the box region for the time-series, they are reduced as shown in Figure 11.  
508 Scaling lightning produces better agreement with the corrected TES O<sub>3</sub> data for October, but  
509 differences remain in late November and early December.

510  
511 Precipitation histograms (as in Figure 7) for multiple locations throughout Indonesia and New  
512 Guinea indicate much more precipitation in the second half November than in the first, which  
513 agrees with the decrease in CO observed during November (Figure 5), and with the increase in  
514 convection in late November that is discussed below (Section 3.6). Assuming that lightning is  
515 coincident with local precipitation, we re-calculate scale factors for October and November  
516 taking  $f_{\text{mon}}$  as  $\frac{1}{2}(f_1+f_2)$  where  $f_1$  and  $f_2$  are factors for the first and second half of each month.  
517 Since October lightning is weak, rescaling its lightning is less important than November;  
518 however, we assume factors of  $f_1=1$  and  $f_2=0.20$  for October and  $f_1=1$  and  $f_2=1.80$  for November,  
519 which when averaged over the month, match the monthly factors. (December lightning was not  
520 re-scaled.)

521  
522 Changes to O<sub>3</sub> as a result of modifying biomass burning emissions and lightning emissions are  
523 not necessarily additive, so we ran the model applying both the lightning scaling and the GFED  
524 increase. Results in Figure 11 show that this run correctly simulates the continual increase in O<sub>3</sub>  
525 during the first half of November in the LT, but still results in a discrepancy for the remainder of  
526 the month and early December. Comparisons between O<sub>3</sub> from this model run and sondes  
527 (Figure 2) also indicates improvements for the Kuala Lumpur and Java stations, but almost no  
528 change for Samoa.

### 529 530 **3.5 Water Vapor**

531  
532 *Chandra et al.* [1998] and others have shown that during the 1997 El Niño, high O<sub>3</sub> coincided  
533 with low H<sub>2</sub>O vapor (at 215 hPa) and weak convection. We demonstrated this inverse  
534 relationship between O<sub>3</sub> and H<sub>2</sub>O anomalies in the LT in Figure 3. Water vapor increases the  
535 rate of O<sub>3</sub> destruction by producing O(<sup>1</sup>D) radicals to react with H<sub>2</sub>O to form HO<sub>x</sub>, but HO<sub>x</sub>  
536 contributes to O<sub>3</sub> production when sufficient NO<sub>x</sub> is present. Although these mechanisms work

537 in opposite directions, for low  $\text{NO}_x$  ( $\sim < 0.10$  ppb),  $\text{O}_3$  destruction dominates, thus increased  $\text{H}_2\text{O}$   
538 decreases  $\text{O}_3$ , while if  $\text{NO}_x$  is higher,  $\text{O}_3$  production dominates, thus increased  $\text{H}_2\text{O}$  increases  $\text{O}_3$   
539 [Klonecki and Levy, 1997].

540  
541 The time evolution of  $\text{H}_2\text{O}$  vapor in TES and the model is shown in Figure 6. After filtering the  
542 TES data to remove extreme outliers, there is very good agreement in the LT and UT for 2005  
543 and 2006 (with the exception of late September 2005, which only had a single TES global  
544 survey, shown in Table 2), although there is a small systematic difference in the LT from  
545 October to December 2006, during which time GEOS-4 is higher than TES by  $\sim 5\%$ . Validation  
546 of GEOS-4 humidity indicates that it is similar to that from the European Centre for Medium  
547 Range Weather Forecasting (ECMWF), but GEOS-4 had a UT moist bias over the ocean [Bloom  
548 *et al.*, 2005]. To determine if errors in GEOS-4  $\text{H}_2\text{O}$  were impacting  $\text{O}_3$ , we carried out a  
549 simulation with  $\text{H}_2\text{O}$  reduced by 10% in the box region for November and December 2006. This  
550 produced a peak increase in  $\text{O}_3$  of  $\sim 6\%$ , but a mean increase of only 1-2%, suggesting that effects  
551 of  $\text{H}_2\text{O}$  vapor on production and destruction of  $\text{O}_3$  nearly balance.

### 552 553 **3.6 Dynamical Factors**

554  
555 Horizontal winds at 700 hPa for the region are shown for half-month intervals in October and  
556 November 2006 in Figure 12. Although the winds over Java and Borneo are generally westerly  
557 in 2005 (not shown), in 2006 they are westerly only in early October. There is easterly  
558 equatorial flow over Indonesia from late October to late November 2006. The effect of the  
559 change in wind flow in 2006 is also evident in Figure 5 where the high CO air mass is dispersed  
560 northeast toward the Pacific during the first half of October, then subsequently west toward the  
561 Indian Ocean. The dispersion of CO is consistent with the weak winds near the western Pacific  
562 and the Maritime continent. This pattern of weak transport is similar to that during the 1997 El  
563 Niño [Duncan *et al.*, 2003a]. In 2006, the flow from northern Australia in late November also  
564 serves transport biomass burning emissions towards the Indian Ocean.

565  
566 Accurate representation of atmospheric convection in global models is difficult, in part because  
567 convective processes occur on sub-grid scales. GEOS-4 uses the Zhang and McFarlane (ZM)  
568 parameterization [Zhang and McFarlane, 1995] for deep convection with updraft mass flux,  
569 downdraft mass flux and updraft entrainment provided as 6-hour averages. Shallow convection  
570 is parameterized separately based on Hack *et al.* [1994].

571  
572 We tested the effect of convection on CO and  $\text{O}_3$  in the model by globally turning off all three  
573 ZM deep convection parameters in GEOS-4, while shallow convection was not changed. Figure  
574 13 shows the difference between our *Base* run and runs with no convection (but identical water  
575 and lightning) for November 2006 at four model levels. Each half-month period began with the  
576 initial tracer concentrations from the *Base* run to isolate the contribution from convection for that  
577 time period. Convection generally reduces CO in the boundary layer (BL) and LT, but increases  
578 it in the UT up to the base of the tropical tropopause layer (TTL), near 14 km. If a strong surface  
579 CO source is present, as in the beginning of November over Indonesia and the Indian Ocean,  
580 convection lofts the CO up to the UT, largely reducing it in the LT, especially in the BL. In the  
581 absence of a strong CO source, as for late November and the remainder of the year (not shown),  
582 reductions in BL and LT CO are smaller and almost equal in magnitude.

583  
584 The effect of convection on O<sub>3</sub> is nearly opposite that of CO, with convection generally  
585 increasing O<sub>3</sub> in the BL and LT, but decreasing it in the UT and base of the TTL. This can be  
586 understood by assuming that convection directly transports air from the LT (containing low  
587 levels of O<sub>3</sub>) to the UT and the associated mixing transports O<sub>3</sub> rich air from the UT down to the  
588 LT where the O<sub>3</sub> lifetime is shorter; however, Figure 2 indicates that our O<sub>3</sub> profiles are nearly  
589 vertical throughout the troposphere. Furthermore, convection also transports O<sub>3</sub> precursors like  
590 CO and NO<sub>x</sub>, which will reduce LT O<sub>3</sub> and increase UT O<sub>3</sub>. These competing mechanisms,  
591 described in earlier work [Lawrence *et al.*, 2003; Doherty *et al.* 2005], indicate that convection  
592 undoubtedly impacts O<sub>3</sub>, but the net effect depends on the balance between multiple factors. As  
593 noted by Lawrence and Salzmann [2008], such tests have significant limitations, because of the  
594 relationship between parameterized deep convection and the large scale circulation which is not  
595 treated correctly when convection is turned off in the model.

596  
597 Observations tell a clearer story about the relationship between convection and O<sub>3</sub> in our region  
598 of interest. During El Niño, when there is weaker convection than normal over the maritime  
599 continent and eastern Indian Ocean, O<sub>3</sub> is higher in the LT and UT; conversely, over the central  
600 Pacific, where convection is stronger than normal, O<sub>3</sub> is lower during El Niño. Here we use  
601 OLR data as a surrogate for deep convective activity, and compare OLR to the time evolution of  
602 the updraft air mass flux in GEOS-4. Observed OLR is interpolated from satellite brightness  
603 temperature data by NOAA [Liebmann and Smith, 1996;  
604 [www.cdc.noaa.gov/cdc/data.interp\\_OLR.html](http://www.cdc.noaa.gov/cdc/data.interp_OLR.html)].

605  
606 Figure 11 shows GEOS-4 updraft air mass fluxes for model levels at ~6.6 km and ~10.0 km  
607 (multiplied by a factor of 4) for the box region used in the time series plots. The mass flux  
608 increases steadily from early October to year end, qualitatively consistent with H<sub>2</sub>O increases in  
609 TES and GEOS-Chem (Figure 6). The OLR data are plotted with the vertical axis reversed,  
610 since low values of OLR indicate high clouds and hence convection. The GEOS-4 OLR line  
611 resembles the updraft mass flux, with a decrease beginning in early October and continuing to  
612 the end of 2006, consistent with strengthening convection. NOAA OLR is systematically lower  
613 than GEOS-4 OLR, but more importantly it hardly changes in October, then decreases steadily  
614 from November to year end. Assuming some consistency between GEOS-4 convection and  
615 OLR implies that GEOS-4 convection starts to increase about a month too early.

616  
617 Figure 14 shows anomaly maps of GEOS-4 and NOAA OLR at half-month intervals, indicating  
618 many similarities between the OLR data sets. Increased OLR (decreased convection) is found  
619 over most of the Indonesia and New Guinea region in late 2006, with a larger and more  
620 contiguous positive anomaly in the NOAA OLR than in the GEOS-4 OLR. This implies that the  
621 reduction in convection in late 2006 during El Niño was not large enough in the model. There are  
622 even small areas north of the equator in late October and early November where OLR is lower in  
623 2006 than in 2005 in the model (implying increased convection in 2006), but not in the NOAA  
624 OLR. A direct comparison of GEOS-4 and NOAA OLR in 2006 (Figure 15) also implies that  
625 there is too strong convection in the model north of the equator from late October until late  
626 November, except over land. (GEOS-4 OLR was reduced by 13 W/m<sup>2</sup> based on the mean offset  
627 from NOAA OLR in Figure 11.) The OLR data imply that GEOS-4 convection is too weak over

628 Java, Borneo and New Guinea, which is consistent with the underestimate of lightning in this  
629 region.

630

631 Too vigorous convection in GEOS-4 during November and December, the months with most  
632 active convection in 2006, is likely responsible for the underestimate of O<sub>3</sub> (Figures 1 and 11),  
633 and for the underestimate of the O<sub>3</sub> anomaly (Figure 3). The underestimate of the anomaly is  
634 most obvious north of the equator, the area with the largest mismatch between model and NOAA  
635 OLR, but there is also an underestimate south of the equator. Overly vigorous convection in a  
636 normal year, when the convection is very active anyway, appears to be less of a problem for  
637 model O<sub>3</sub>, since the model reproduces observed O<sub>3</sub> profiles in 2005, as shown by the sonde data  
638 comparisons in Figure 2 and by TES comparisons in Figure 6.

639

640 Both the GEOS-4 and NOAA OLR show decreased OLR (increased convection) over the  
641 central Pacific. Increased convection here is responsible for the co-located reduction in O<sub>3</sub>  
642 during El Niño [*Chandra et al.*, 1998]. We noted earlier that both the TES data and the model  
643 show a negative O<sub>3</sub> anomaly in October (east of the date-line), but that it disappears in  
644 November, and returns weakly in December. The OLR data show only a weak convection  
645 anomaly east of the date-line in early October. It weakens for a month, then strengthens until the  
646 end of the year.

647

648 The most prominent negative OLR anomaly is over the western Indian Ocean and east equatorial  
649 Africa in late November and December. The increase in convection in 2006 contributed to the  
650 prominent negative anomaly in O<sub>3</sub> in December in eastern Africa seen in the TES data and the  
651 model (Figure 3).

652

### 653 **3.7 Soil NO<sub>x</sub> Emissions**

654

655 Another factor contributing to O<sub>3</sub> that may not be well-represented in the model is the release of  
656 NO<sub>x</sub> from soil, which occurs both gradually and as a pulse at the onset of heavy rains. Recent  
657 estimates of soil NO<sub>x</sub> emissions suggest a global source of 8.9 TgN/yr [*Jaeglé et al.*, 2005],  
658 which is much larger than most earlier estimates. In northern Africa, which accounts for 30% of  
659 global soil NO<sub>x</sub>, pulses have been shown to last for 1-3 weeks after the onset of rain [*Jaeglé et*  
660 *al.*, 2004].

661

662 GEOS-Chem accounts for soil NO<sub>x</sub> emissions based on the approach of *Yienger and Levy*  
663 [1995], in which a very low, baseline level of emissions are constantly released from wet soil,  
664 but at the onset of rain, this background is multiplied by a scale factor to simulate a pulse of NO<sub>x</sub>  
665 emissions, which then decreases exponentially with time. The pulse strength depends on the  
666 rainfall rate with factors of 5 (relative to baseline emissions) for a sprinkle (1-5 mm/day), 10 for  
667 a shower (5-15 mm/day) and 15 for heavy rain (>15 mm/day). *Yienger and Levy* [1995] state  
668 that the range of likely scale factors spans 10-100. To investigate the effect of a hypothetical  
669 large NO<sub>x</sub> pulse, we ran the model for November with a factor of 10 increase in soil NO<sub>x</sub> coming  
670 from land within the same box used to scale lightning (Figure 9). This increase is minimal in the  
671 absence of precipitation, but increases the model scale factors to 50, 100, and 150 for a sprinkle,  
672 a shower, and heavy rain, respectively. Figure 16 shows the difference in O<sub>3</sub> between this run  
673 (*SoilNOx10*) and the *Base* run. Ozone increases first occur over land with the largest intensity

674 originating from the island of Sulawesi (east of Borneo), but transport carries O<sub>3</sub> and its  
675 precursors eastward, such that in the second half of November, the increase over Java and  
676 Borneo is on the order of 10 ppb in the LT and UT. Evidently, a larger increase in soil NO<sub>x</sub>  
677 emissions after rainfall would remove some of the discrepancy in Figure 11 in late November  
678 and would improve the spatial pattern of the model anomaly in Figure 3 in November (and likely  
679 December) in the equatorial region.

680

#### 681 **4. Discussion and Conclusions**

682

683 A moderate El Niño and the positive phase of the IOD were coincident in late 2006 for the first  
684 time since 1997 and only the fourth time in ~50 years. From mid-September to mid-November,  
685 Indonesia experienced severe ENSO-IOD-induced drought permitting intense biomass burning  
686 in southern Borneo [*Field and Shen, 2008*]. This burning decreased abruptly in mid-November  
687 as heavy rains began. TES, which provides simultaneous, coincident, nadir measurements of  
688 CO, O<sub>3</sub> and H<sub>2</sub>O from space, observed elevated O<sub>3</sub> and CO above Indonesia and the eastern  
689 Indian Ocean during late 2006 [*Logan et al., 2008*]. Carbon monoxide exceeded 200 ppb in the  
690 LT in the area of peak intensity throughout October and early November. Ozone observations  
691 exceeded values from 2005 (a neutral ENSO year) by 12-18 ppb in the LT and 15-24 ppb in the  
692 UT from October to mid-December, but the O<sub>3</sub> anomaly was not entirely coincident in space and  
693 time with the elevated CO.

694

695 GEOS-Chem model simulations exhibit the main features in tropospheric CO and O<sub>3</sub> that were  
696 observed by TES during late 2006, indicating that most important chemical and physical  
697 processes are understood and are accounted for by the model. This study is the first to use  
698 simultaneous measurements of tropospheric CO, O<sub>3</sub> and H<sub>2</sub>O to evaluate model results. The CO  
699 data enabled us to test the GFED bottom-up estimates of CO emissions from the massive  
700 Indonesian fires in 2006. We confirm previous findings which suggest that elevated O<sub>3</sub> during  
701 an El Niño results from a combination of biomass burning and dynamical factors [*Hauglustaine*  
702 *et al., 1999; Sudo and Takahasi, 2001; Thompson et al., 2001; Chandra et al., 2002*], but we  
703 investigate the causes of O<sub>3</sub> changes in greater detail. By examining CO and O<sub>3</sub> changes at  
704 higher spatio-temporal resolution than in earlier studies, and by investigating the roles of  
705 biomass burning, lightning, winds, convection, H<sub>2</sub>O, and soil NO<sub>x</sub>, we uncover some limitations  
706 in the model and in our understanding of the detailed mechanisms for elevated O<sub>3</sub> and CO.

707

708 The decrease in CO in the LT in late November and December occurs more rapidly in the model  
709 than in TES observations, even with the use of 8-day GFED biomass burning emissions. This  
710 likely occurs because the GFED inventory is based on MODIS fire counts, which do not account  
711 for CO emissions from smoldering stage of fires, which are significant for peat fires in Borneo. It  
712 was necessary to increase GFED emissions for Indonesia by a factor of 3 in November 2006 to  
713 obtain consistency with the time evolution of the TES CO observations.

714

715 It proved more difficult to reproduce the temporal and spatial evolution of the O<sub>3</sub> anomaly in late  
716 2006; the model does best in October. The adjusted GFED emissions in November improve the  
717 model simulation of O<sub>3</sub> in early November, but the model starts to decrease two week too early,  
718 in late November, and thereafter is lower than TES observations. We explored if this could be

719 caused by the higher lightning NO<sub>x</sub> emissions in 2006, as proposed in our earlier work [*Logan et*  
720 *al.*, 2008].

721  
722 The LIS data show that lightning flash rates were as much as 200% higher in November and  
723 December 2006 than in 2005, but lower in October. Model lightning is derived from cloud top  
724 heights which seem to be underestimated over Indonesia and the neighboring islands in late 2006  
725 (based on the OLR analysis), leading to underestimates in lightning NO<sub>x</sub>. By adjusting the model  
726 lightning in 2006 based on LIS observations and the timing of precipitation, differences in  
727 lightning NO<sub>x</sub> between 2005 and 2006 are shown to make a modest contribution (a few ppb) to  
728 the model O<sub>3</sub> anomaly. Sensitivity runs with no NO<sub>x</sub> from lightning show that this source of NO<sub>x</sub>  
729 contributes about 5-15 ppb O<sub>3</sub> in total in the equatorial band around Indonesia, with the largest  
730 contribution in the UT. The model run with adjusted lightning and adjusted GFED emissions  
731 matches the temporal evolution of LT O<sub>3</sub> very well in the equatorial box with highest CO until  
732 late November, when model O<sub>3</sub> starts to decrease two weeks early. In the UT, the model  
733 matches the temporal evolution of O<sub>3</sub> fairly well, but is too low by ~10 ppb from late October  
734 onwards.

735  
736 Convective transport remains one of the most challenging processes for global models to  
737 represent accurately, yet convection changes during El Niño are very important contributors to  
738 the O<sub>3</sub> anomalies. Comparison of model OLR with that derived from observations implies that  
739 the convection is too strong in the model in 2006 in the Indonesian region, except over land  
740 where the model cloud top heights are too low (consistent with the lightning problem). Maps of  
741 NOAA OLR show that convection is most active near the Equator, where the O<sub>3</sub> anomaly is  
742 missing in December. Overly vigorous convection in the model appears to be the cause of the  
743 disparity between the observed and modeled O<sub>3</sub> anomaly in the eastern Indian Ocean and  
744 Indonesia from mid-November onwards, when convection starts to increase. Soil NO<sub>x</sub> emissions  
745 after the onset of rain could also play a role in the disparity.

746  
747 The asymmetric dipole anomaly relationship between O<sub>3</sub>, H<sub>2</sub>O, and convection observed during  
748 past El Niño events [*Chandra et al.*, 1998] is evident in 2006, with an inverse relationship for  
749 most of the H<sub>2</sub>O and O<sub>3</sub> anomalies in both TES observations and the model (Figure 3). The  
750 Indonesian node of the dipole was strongest in October and decreased in November and  
751 December. The dipole node over the central Pacific (negative for O<sub>3</sub> and positive for H<sub>2</sub>O) was  
752 present in October, temporarily weakened in November, and reappeared in December in both the  
753 model and observations.

754  
755 The contribution of biomass burning emissions to the O<sub>3</sub> anomaly in the LT is generally less than  
756 10 ppb, reaching more than 15 ppb only in October immediately downwind of the fires in  
757 Borneo. It is primarily located from the equator to 10°S in October, but extends further south in  
758 November. By contrast, the anomaly related to dynamical factors is largest south of 10°S, and is  
759 more extensive. It may be that the effect of the fire related anomaly is underestimated in the  
760 model because of the overly vigorous convection that starts too early in the model. In the region  
761 with highest CO, biomass burning emissions contribute ~45% of the O<sub>3</sub> anomaly in October and  
762 late November, ~75% in early November, and only 10% in December (Table 3).

763

764 The potential contribution to O<sub>3</sub> from emissions of NO<sub>x</sub> from soil was investigated, since these  
765 emissions increase with the onset of rain [Jaeglé *et al.*, 2004; 2005]. The magnitude of increase  
766 is related to the strength of rain, with an uncertainty of at least an order of magnitude [Yienger  
767 and Levy, 1995]. Increasing soil NO<sub>x</sub> emissions by a factor of 10 showed significant increases in  
768 O<sub>3</sub> in late November, suggesting this could be a contributing factor to the low O<sub>3</sub> in the model,  
769 particularly the underestimate in the equatorial band in November and December. This should be  
770 investigated in future work making use of available satellite measurements of NO<sub>2</sub> as a  
771 constraint.

772  
773 Both the TES data and the model show a large negative O<sub>3</sub> anomaly (10-20 ppb) in equatorial  
774 Africa and the western Indian Ocean in December that is collocated with a positive H<sub>2</sub>O anomaly  
775 and a positive convection anomaly (Figures 3 and 14). This feature starts to develop in  
776 November. The short rain season in eastern equatorial Africa is in October to December, and  
777 there was a drought in this region in late 2005 and heavy rainfall and severe flooding in late 2006  
778 [Shein *et al.*, 2006; Arguez, *et al.*, 2007]. It is likely that this event was related more to the  
779 dynamics of the Indian Ocean basin rather than simply a response to El Niño, based on analyses  
780 of previous extreme rainfall events in this region [Webster *et al.*, 1999; Saji *et al.*, 1999]. The  
781 vigorous convection in late 2006 evidently caused the large decrease in O<sub>3</sub> relative to conditions  
782 in 2005. The O<sub>3</sub> anomaly extends further west than the H<sub>2</sub>O anomaly in this region of easterlies,  
783 in the TES data and in the model.

784  
785 There has been considerable analysis of the effects of the 1997 El Niño [for example Chandra *et*  
786 *al.*, 1998; Hauglustaine *et al.*, 2001; Sudo and Takahashi, 2001; Thompson *et al.*, 2001; Duncan  
787 *et al.*, 2003a], because of the important role that ENSO plays in tropical atmospheric chemistry  
788 as discussed in the Introduction. The present work provides a more detailed analysis of the  
789 effects of the 2006 El Niño than was possible for the 1997 event, because of the availability of  
790 satellite observations of CO, O<sub>3</sub>, H<sub>2</sub>O, fires, and lightning. While not as strong as the El Niño in  
791 1997, the 2006 event shared similarities such as the IOD influence. The coincident IOD appears  
792 to reinforce some El Niño effects for the region such that the combination produces an impact  
793 similar to a stronger El Niño than the Pacific SST anomalies would suggest, including the severe  
794 drought and very intense biomass burning in Borneo. ENSO is the dominant mode of tropical  
795 tropospheric variability and contemporary El Niño conditions in the tropics may provide a  
796 preview of future anthropogenically-induced climate warming, thus it is important to use  
797 observed changes in atmospheric composition induced by these events to challenge and improve  
798 global models.

1137 **Figure Captions**

1138 Figure 1: Lower tropospheric (LT, 825-511 hPa) CO, O<sub>3</sub> and H<sub>2</sub>O for October, November and  
1139 December 2006 from TES (left column), the GEOS-Chem *Base* run (GEOS-4 for H<sub>2</sub>O) with the  
1140 TES averaging kernel applied (middle column), and the model wAK – TES difference (right  
1141 column).

1142  
1143 Figure 2: Comparison between GEOS-Chem O<sub>3</sub> profiles (dashed lines) from the *Base* run and  
1144 ozonesonde measurements (solid lines) at Java, Kuala Lumpur (KL) and Samoa during the  
1145 relevant months of 2005 and 2006. The *ScldLight-3xE* run (dotted lines) is also shown for the  
1146 October to December 2006 plots and lies close to the *Base* run profiles.

1147  
1148 Figure 3: LT CO, O<sub>3</sub> and H<sub>2</sub>O 2006-2005 differences or anomalies from TES and the GEOS-  
1149 Chem *Base* run (GEOS-4 for H<sub>2</sub>O) wAKs for October, November and December.

1150  
1151 Figure 4: CO and O<sub>3</sub> anomalies based on GEOS-Chem *2006e05* wAK (2006 runs using 2005  
1152 GFED emissions) minus 2005 *Base*. The primary CO anomaly from Figure 3 is no longer seen,  
1153 while the main O<sub>3</sub> anomaly from Figure 3 is still present but reduced in size (especially in  
1154 November) and shifted south of the equator.

1155  
1156 Figure 5: CO from TES and the GEOS-Chem *Base* run wAK shown on half-month intervals for  
1157 October and November 2006 (Table 2 gives exact time periods). The rectangle denotes the 5°N-  
1158 11°S, 91.25-121.25°W region of the LT which is averaged for time series line plots (Figures 6  
1159 and 11). The dramatic change in CO between the first and last half of November is evident.

1160  
1161 Figure 6: The time evolution of TES and the GEOS-Chem *Base* run for CO, O<sub>3</sub> and H<sub>2</sub>O in late  
1162 2005 and 2006. GFED CO emissions are shown corresponding to the axis on the right. The  
1163 GEOS-Chem *2006e05* and *3xE* runs are also shown. All values are half-month means plotted at  
1164 0.25 and 0.75 of each month and the TES averaging kernel has been applied to the model data.

1165  
1166 Figure 7: GFED CO emissions (2°x2.5° resolution) originating from the region of Indonesia and  
1167 New Guinea (top panel). Regional CO emissions from 2005 and 2006 are plotted on the 4<sup>th</sup> day  
1168 of each 8-day interval (2<sup>nd</sup> panel). Precipitation at Palangkaraya and Banjarmasin in late 2006  
1169 (from <http://www.tutiempo.net>, lower panels).

1170  
1171 Figure 8: Separating the effects of emissions and meteorology. The left column shows the total  
1172 monthly 2006-2005 anomalies for the LT calculated from the *3xE* GEOS-Chem run for 2006  
1173 (increased biomass burning emissions in November 2006) and the *Base* run for 2005. The  
1174 middle column shows the contribution directly from the *3xE* biomass burning enhancement in  
1175 2006 relative to 2005 biomass burning emissions (2006 *3xE* – 2006 *E05*). The right column  
1176 shows the contribution to the anomaly from other factors (2006 *E05* – 2005 *base*, which is also  
1177 the difference of the other two columns) and is equivalent to the right column in Figure 4.

1178  
1179 Figure 9: GEOS-Chem 2006 lightning flash rate (left), GEOS-Chem 2006-2005 lightning  
1180 anomalies (middle), and Lightning Imaging Sensor (LIS) lightning anomalies (right), both in  
1181 percent. The rectangle shows the region (9°N-13°S and 93.75-151.25°E) for which model  
1182 lightning is too low necessitating an increase.

1183  
1184 Figure 10: Net O<sub>3</sub> from lightning in the UT and LT for October-December determined by taking  
1185 the difference between ozone in *Base-13* minus *NoLight* for 2005 (left) and 2006 (middle). The  
1186 2006-2005 difference between the *NoLight* runs (right) shows a strong resemblance to the overall  
1187 O<sub>3</sub> anomaly in Figure 3.  
1188

1189 Figure 11: Time evolution of O<sub>3</sub> from TES and the GEOS-Chem *Base*, *3xE*, *SclLight*,  
1190 *SclLight-3xE* and *SoilNOx10* runs for the UT and LT (upper and middle panels). The TES  
1191 averaging kernel has been applied to the model data. GEOS-4 updraft mass fluxes for model  
1192 sigma levels near 10 km (multiplied by 4) and 6.6 km are also shown with GEOS-4 and NOAA  
1193 Outgoing Longwave Radiation (OLR) (bottom panel). The GEOS-4 data correspond to the same  
1194 region (11°S-5°N, 91.25-121.25°E) region as the TES and GEOS-Chem data, but the NOAA  
1195 OLR averages are for a slightly different region (11.25°S-6.25°N, 91.25-121.25°E) due to its  
1196 different grid. All values are half-month means plotted at 0.25 and 0.75 of each month.  
1197

1198 Figure 12: GEOS-4 horizontal winds at 700 hPa for half-month intervals in 2006.  
1199

1200 Figure 13: CO and O<sub>3</sub> contributions from convection in GEOS-Chem, determined as the *Base*  
1201 run minus *NoConvection* run. Panels show model levels near the base of the tropopause (top  
1202 row), in the UT (second row), LT (third row) and boundary layer (bottom row) for the first and  
1203 second halves of November 2006. Approximate altitudes corresponding to GEOS-4 sigma levels  
1204 are given on the right.  
1205

1206 Figure 14: Differences in OLR (2006-2005) from GEOS-4 and NOAA data for October to  
1207 December in half-month intervals.  
1208

1209 Figure 15: GEOS-4 – NOAA OLR for November-December 2006 after applying a bias  
1210 correction of 13 W/m<sup>2</sup> to account for differences between the OLR datasets (see Figure 11).  
1211

1212 Figure 16: Ozone change resulting from an increase in soil NO<sub>x</sub> emissions by a factor of 10, for  
1213 the first and second halves of November near the base of the tropopause, UT, LT and BL. The  
1214 change was calculated from the difference of *SoilNOx10* – *Base*. Approximate altitudes  
1215 corresponding to GEOS-4 sigma levels are given on the right.  
1216

1217 **Tables**

1218

1219 Table 1: Summary of GEOS-Chem simulations<sup>a</sup>.

1220

<b>Run-name</b> <b>Abbreviation</b>	<b>Description</b>	<b>Date range</b>
<i>Spin</i>	Initialization	20041201 - 20050831
<i>Base</i>	Baseline run (using modified version 7-04-10)	20050901 - 20061231
<i>2006e05</i>	Run with 2005 GFED emissions	20060101 - 20061231
<i>3xE</i>	Run with November GFED emissions increased by a factor of 3 in a box region	20061101 - 20061231
<i>ScldLight</i>	Run with monthly scaled lightning in a box region	20061001 - 20061231
<i>ScldLight-3xE</i>	Run with bi-monthly scaled lightning in a box region and increased November GFED emissions	20061001 - 20061231
<i>NoConvection</i>	Run with deep convection turned off, with each half-month initialized from the baseline run	20061101 - 20061115 20061116 - 20061130 20061201 - 20061215 20061216 - 20061231
<i>Base-13</i>	Baseline run with v7-04-13	20050901 - 20051231 20060901 - 20061231
<i>NoLight</i>	Run with global lightning turned off (v7-04-13)	20050901 - 20051231 20060901 - 20061231
<i>SoilNOx10</i>	Run with soil NO <sub>x</sub> emissions increased by a factor of 10 in a box region	20061101 - 20061130

1221

1222 <sup>a</sup> Simulations used a modified version 7-04-10 unless otherwise stated.

1223

1224 Table 2: Nominal half-month periods<sup>a</sup>

1225

<i>Nominal Period</i>	<i>Exact TES date-time span</i>	<i>Global Surveys</i>
200509 1 <sup>st</sup> half	Sep 02 (8:40:25) – Sep 13 (11:38:57)	6
200509 2 <sup>nd</sup> half	Sep 30 (9:04:58) – Oct 01 (11:26:18)	1
200510 1 <sup>st</sup> half	Oct 02 (8:52:35) – Oct 15 (11:38:49)	7
200510 2 <sup>nd</sup> half	Oct 16 (9:05:08) – Oct 31 (11:39:05)	8
200511 1 <sup>st</sup> half	Nov 05 (8:40:44) – Nov 16 (11:39:15)	6
200511 2 <sup>nd</sup> half	Nov 17 (9:05:34) – Nov 29 (23:17:40)	6.25 <sup>b</sup>
200512 1 <sup>st</sup> half	Dec 07 (8:40:52) – Dec 16 (11:51:36)	5
200512 2 <sup>nd</sup> half	Dec 17 (9:17:54) – Dec 30 (12:03:49)	7
200609 1 <sup>st</sup> half	Sep 09 (9:59:00) – Sep 16 (11:41:55)	4
200609 2 <sup>nd</sup> half	Sep 17 (9:09:35) – Sep 30 (11:34:16)	5
200610 1 <sup>st</sup> half	Oct 01 (9:21:56) – Oct 16 (11:54:09)	8
200610 2 <sup>nd</sup> half	Oct 17 (9:21:49) – Nov 01 (11:53:58)	8
200611 1 <sup>st</sup> half	Nov 02 (9:21:37) – Nov 15 (12:06:06)	7
200611 2 <sup>nd</sup> half	Nov 16 (9:33:44) – Dec 01 (12:05:47)	8
200612 1 <sup>st</sup> half	Dec 02 (9:33:27) – Dec 15 (11:33:56)	7
200612 2 <sup>nd</sup> half	Dec 16 (9:45:55) – Dec 29 (12:30:37)	7

1226 <sup>a</sup> The half-month periods were chosen to balance the need to increase temporal resolution and have  
1227 adequate spatial coverage, without dividing Global Surveys.

1228 <sup>b</sup> The final GS for this time period was interrupted on Nov 29 after less than 7 of the required 26 hours.  
1229 Warm-up of the TES optical bench (for decontamination) occurred in the gap from Nov. 29 to Dec. 7.

1230

1231 Table 3: Contribution from biomass burning to the 2006-2005 O<sub>3</sub> anomaly in the region of high  
 1232 CO, the TES and model anomalies, and their difference<sup>a</sup>.

1233

	<b>Biomass Burning (%)<sup>b</sup></b>		<b>GC Total Anomaly (ppb)<sup>c</sup></b>		<b>TES Total Anomaly (ppb)<sup>d</sup></b>		<b>GC-TES (ppb)</b>	
	<b>LT</b>	<b>UT</b>	<b>LT</b>	<b>UT</b>	<b>LT</b>	<b>UT</b>	<b>LT</b>	<b>UT</b>
<b>September 1-15</b>	25	26	8.3	9.6	13.4	14.3	-5.1	-4.7
<b>September 16-30</b>	61	75	5.3	3.8	7.1	0.9	-1.8	+3.0

<b>December 16-31</b>	9	9	4.0	5.2	8.1	9.1	-4.0	-3.9
<b>Mean</b>	<b>39.4</b>	<b>42.9</b>	<b>11.0</b>	<b>11.9</b>	<b>13.1</b>	<b>14.3</b>	<b>-2.1</b>	<b>-2.4</b>

1234 <sup>a</sup> Results are given for the region 11°S-5°N and 91.25-121.25°E (box in Figure 5)

1235 <sup>b</sup> Based on (2006 *3xE* – 2006*e05*) relative to the model total

1236 <sup>c</sup> GEOS-Chem total is based on (2006 *3xE-ScldLight* – 2005 *Base*)

1237 <sup>d</sup> Based on the bias-corrected TES O<sub>3</sub> anomaly

1238

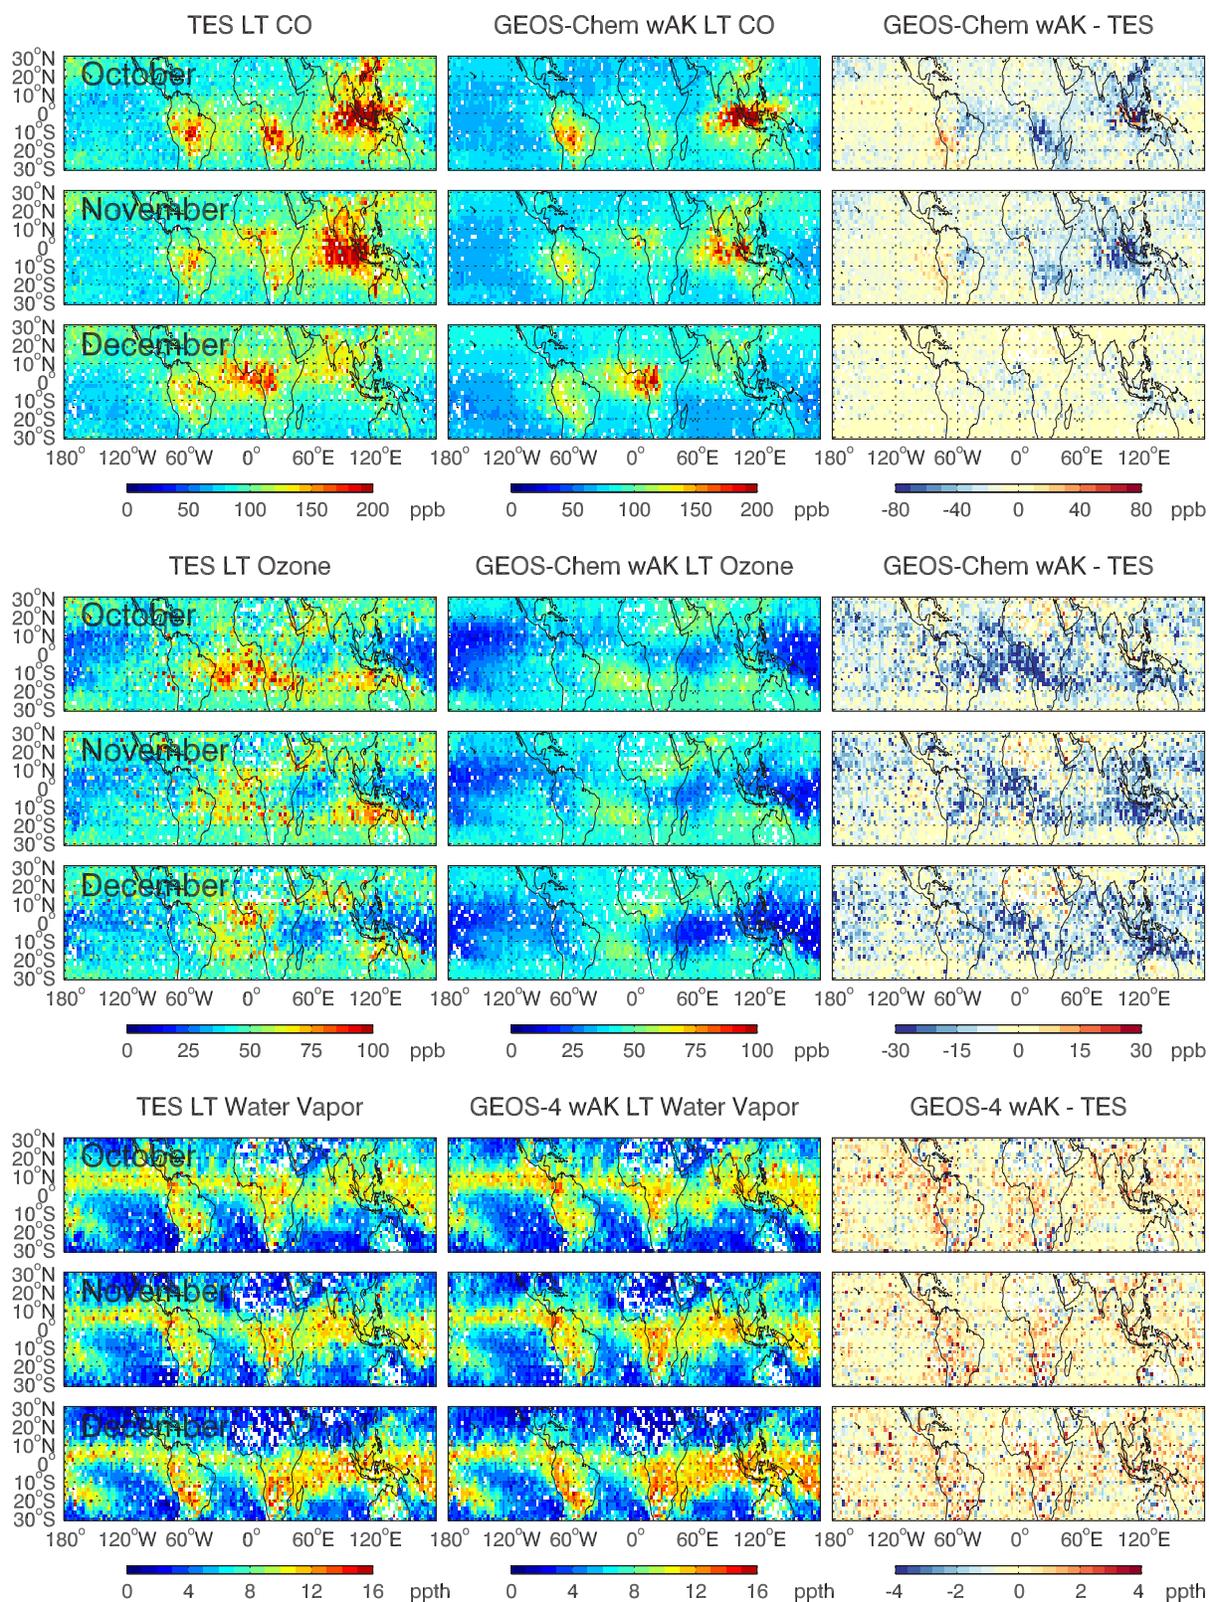

Figure 1: Lower tropospheric (LT, 825-511 hPa) CO, O<sub>3</sub> and H<sub>2</sub>O for October, November and December 2006 from TES (left column), the GEOS-Chem *Base* run (GEOS-4 for H<sub>2</sub>O) with the TES averaging kernel applied (middle column), and the model wAK – TES difference (right column).

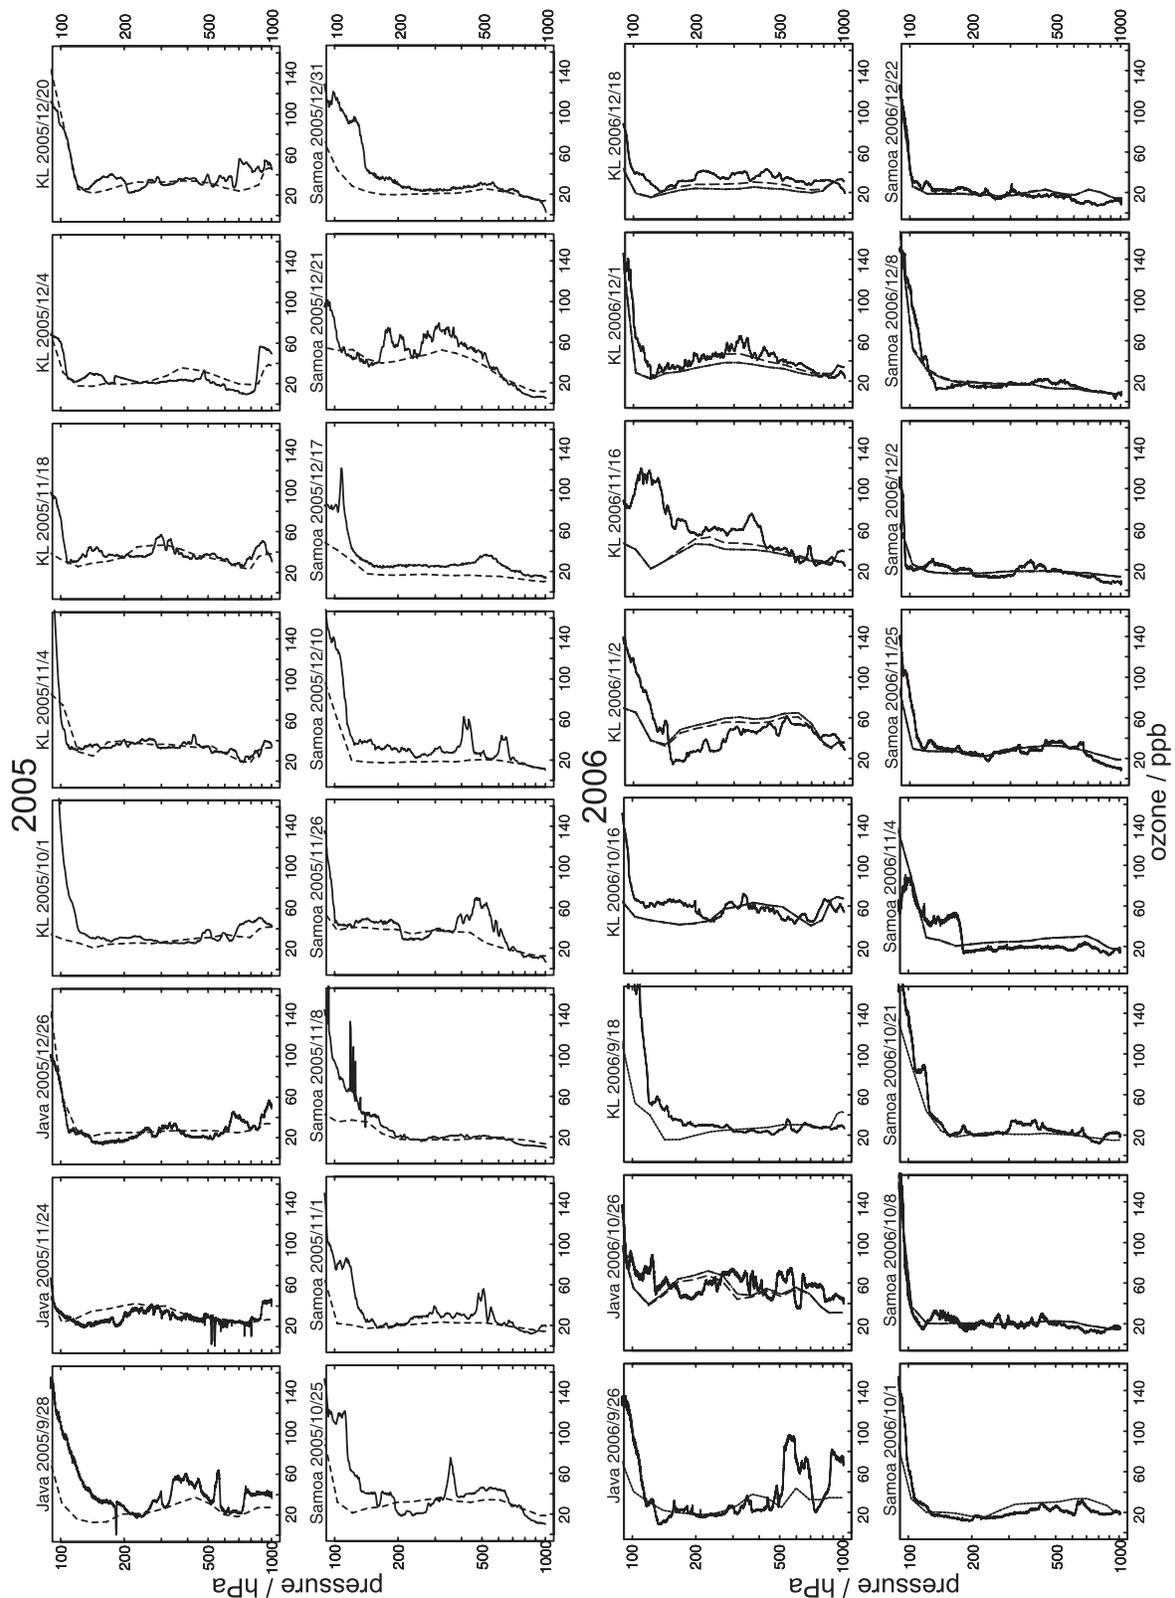

Figure 2: Comparison between GEOS-Chem  $O_3$  profiles (dashed lines) from the *Base* run and ozonesonde measurements (solid lines) at Java, Kuala Lumpur (KL) and Samoa during the relevant months of 2005 and 2006. The *ScldLight-3xE* run (dotted lines) is also shown for the October to December 2006 plots and lies close to the *Base* run profiles.

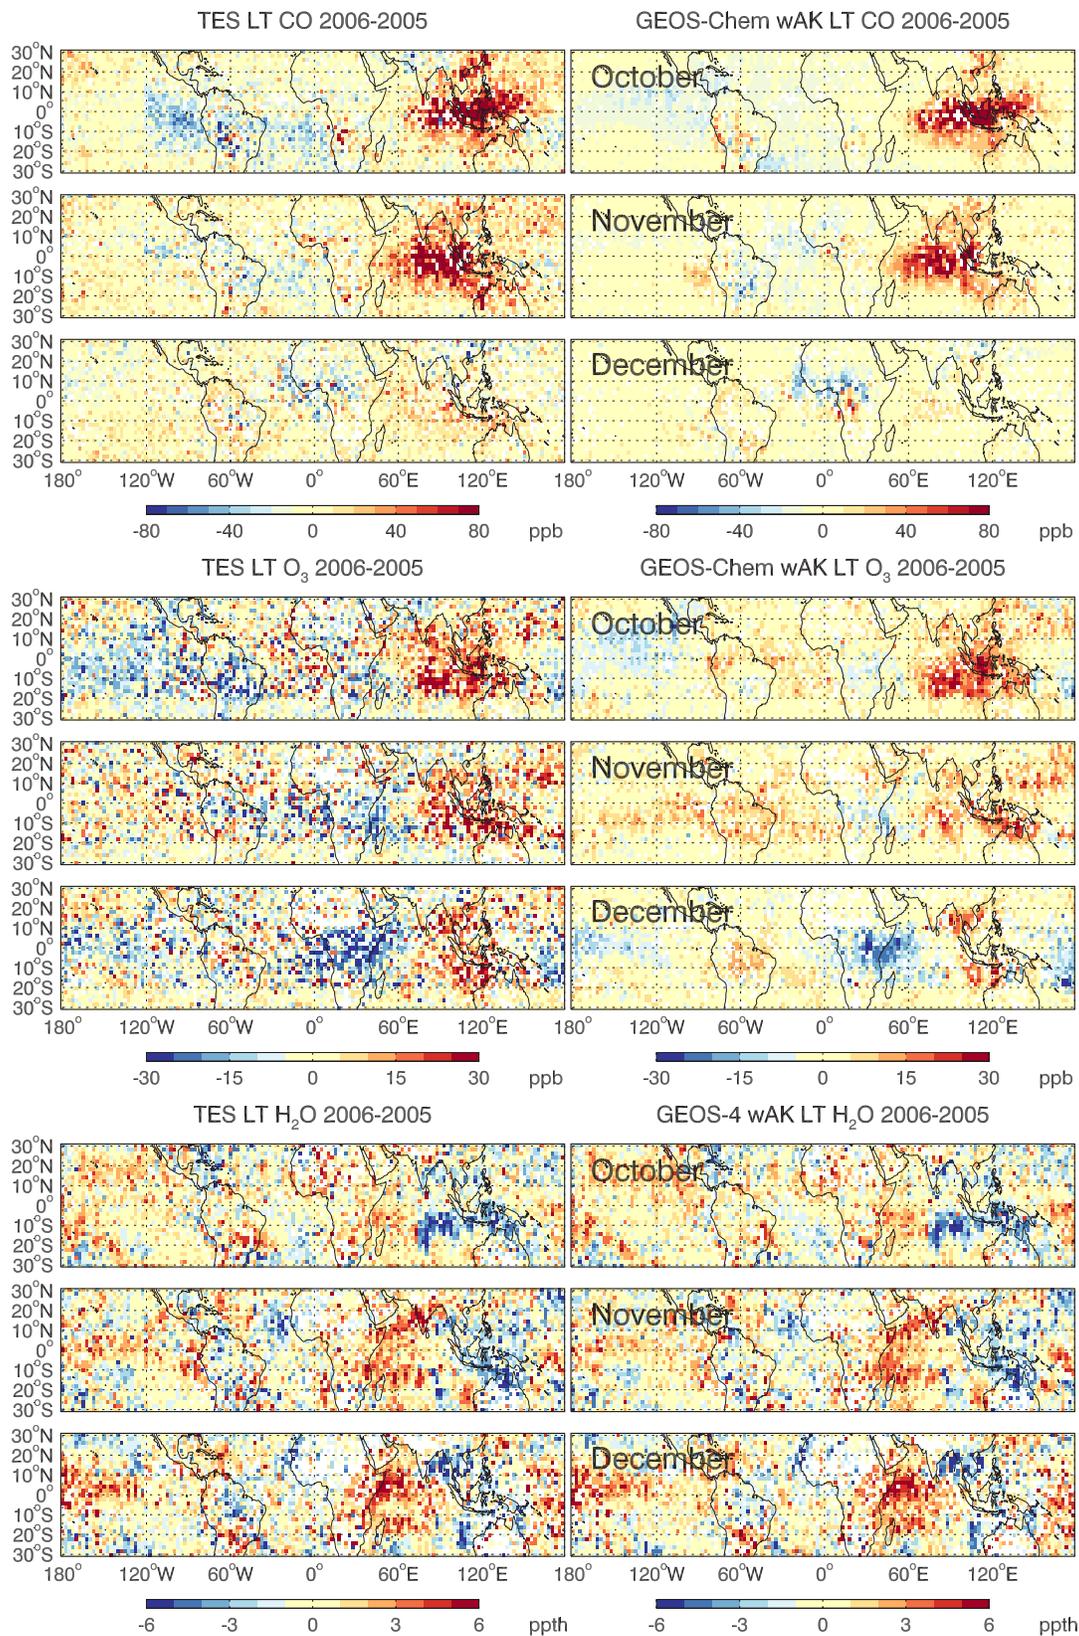

Figure 3: LT CO, O<sub>3</sub> and H<sub>2</sub>O 2006-2005 differences or anomalies from TES and the GEOS-Chem *Base* run (GEOS-4 for H<sub>2</sub>O) wAKs for October, November and December.

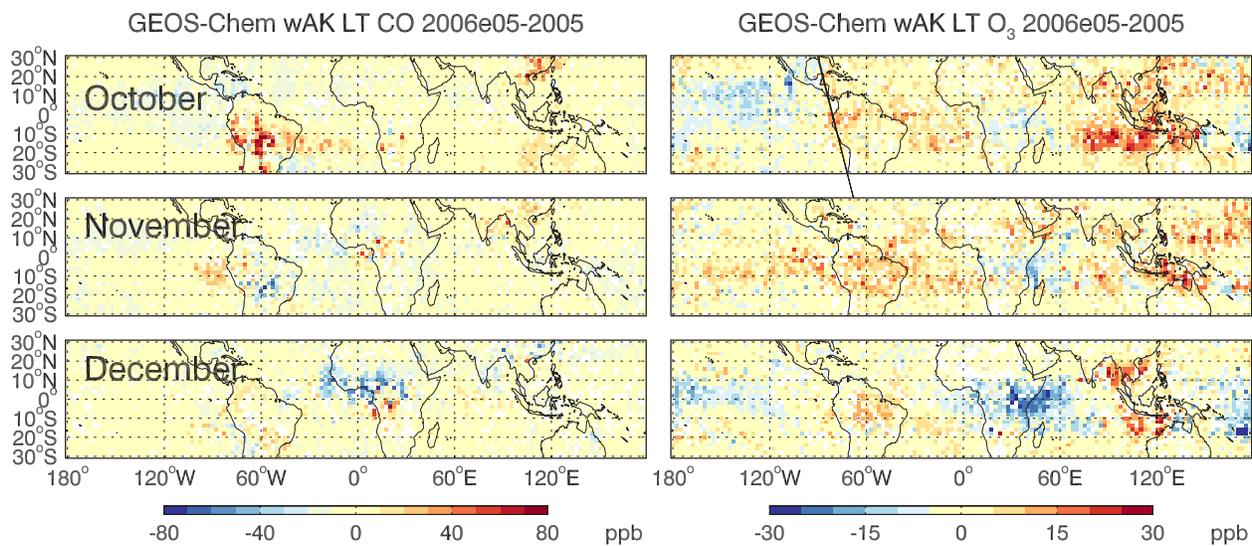

Figure 4: CO and O<sub>3</sub> anomalies based on GEOS-Chem 2006e05 wAK (2006 runs using 2005 GFED emissions) minus 2005 Base. The primary CO anomaly from Figure 3 is no longer seen, while the main O<sub>3</sub> anomaly from Figure 3 is still present but reduced in size (especially in November) and shifted south of the equator.

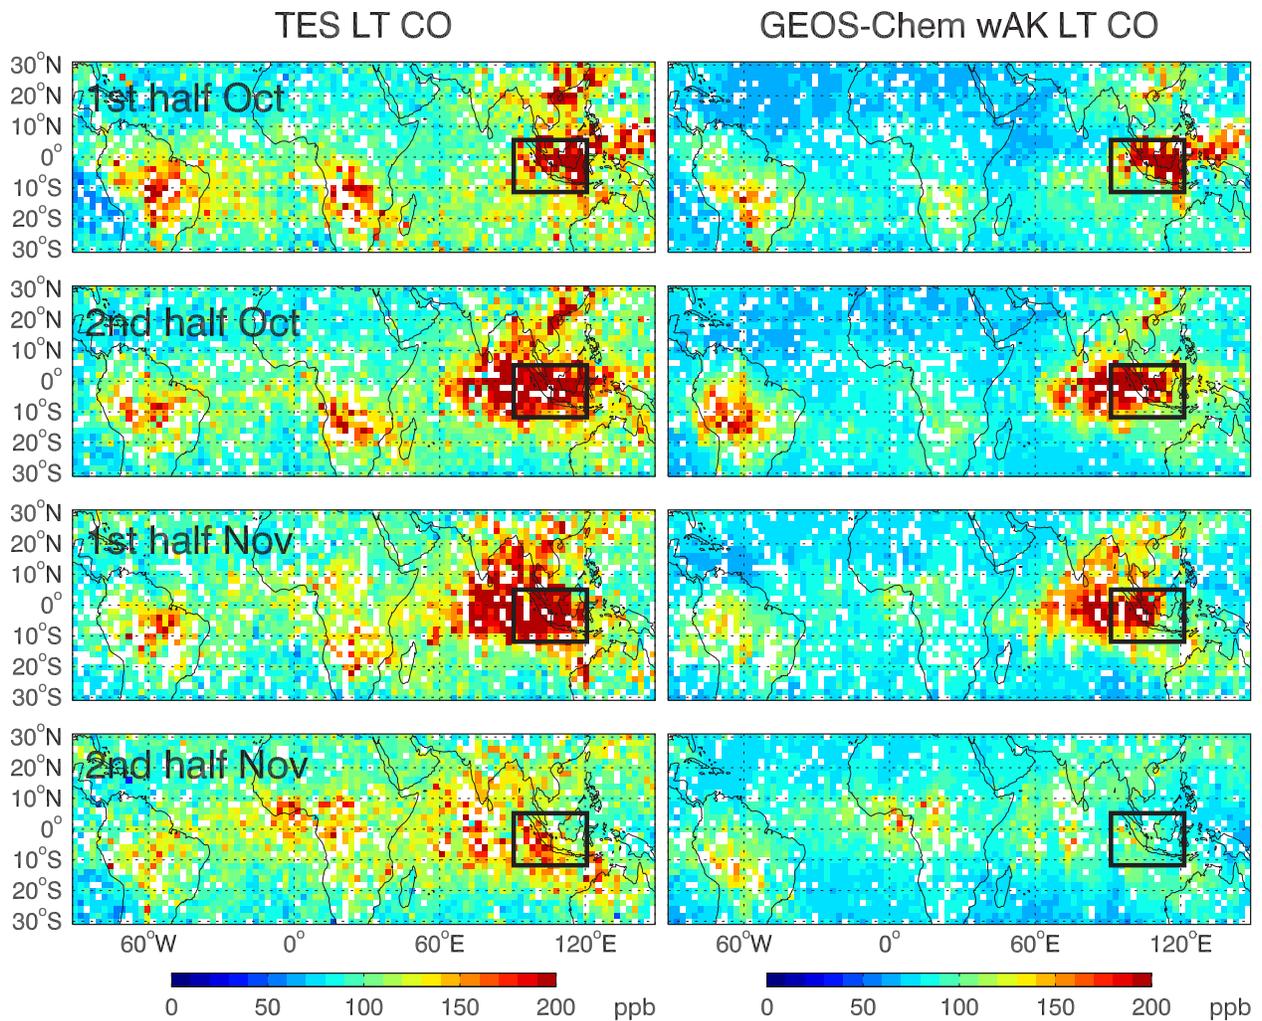

Figure 5: CO from TES and the GEOS-Chem *Base* run wAK shown on half-month intervals for October and November 2006 (Table 2 gives exact time periods). The rectangle denotes the 5°N-11°S, 91.25-121.25°W region of the LT which is averaged for time series line plots (Figures 6 and 11). The dramatic change in CO between the first and last half of November is evident.

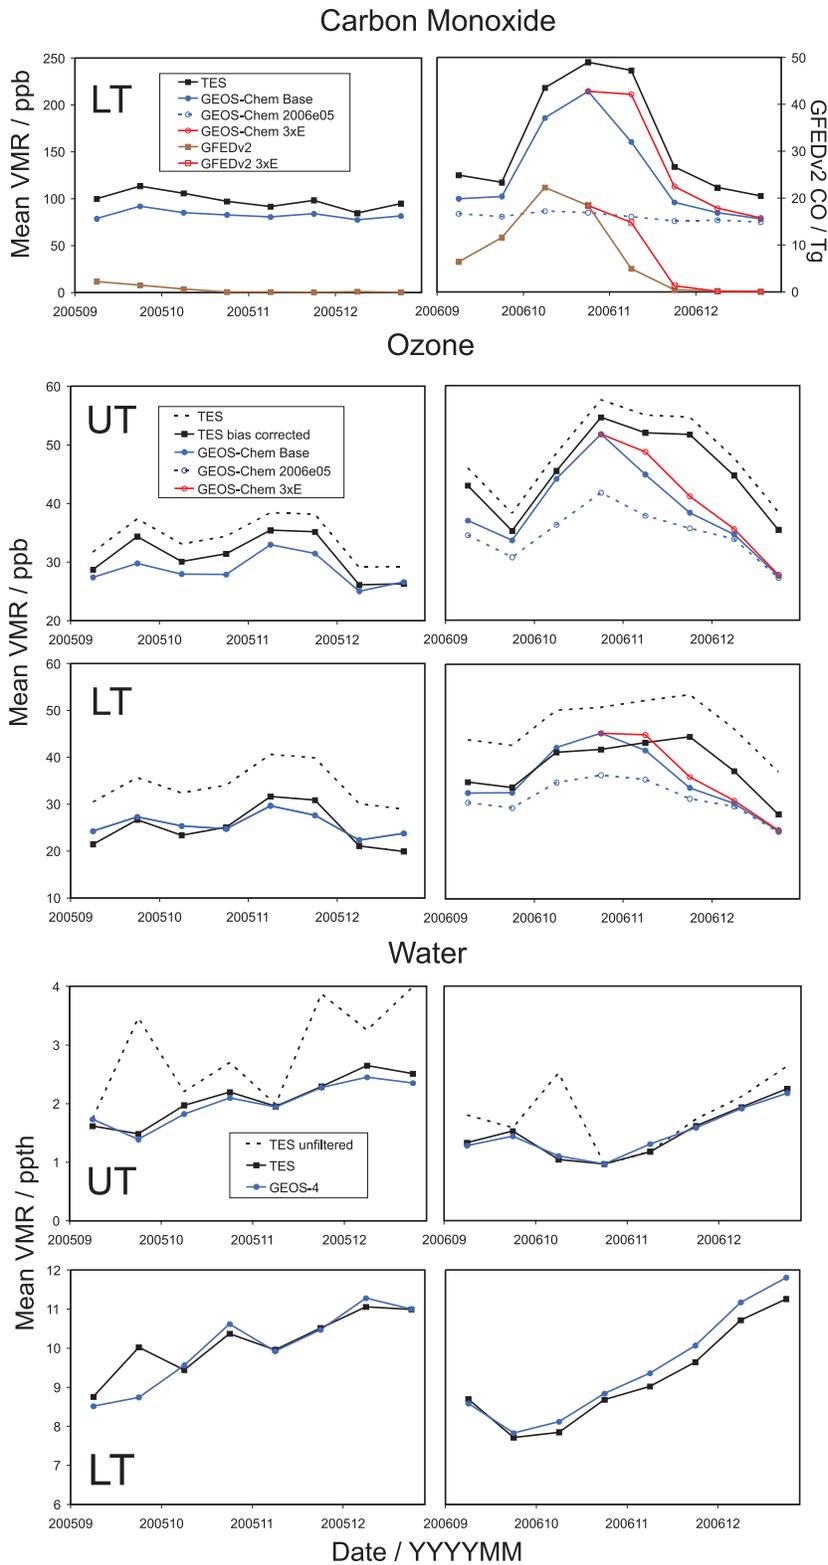

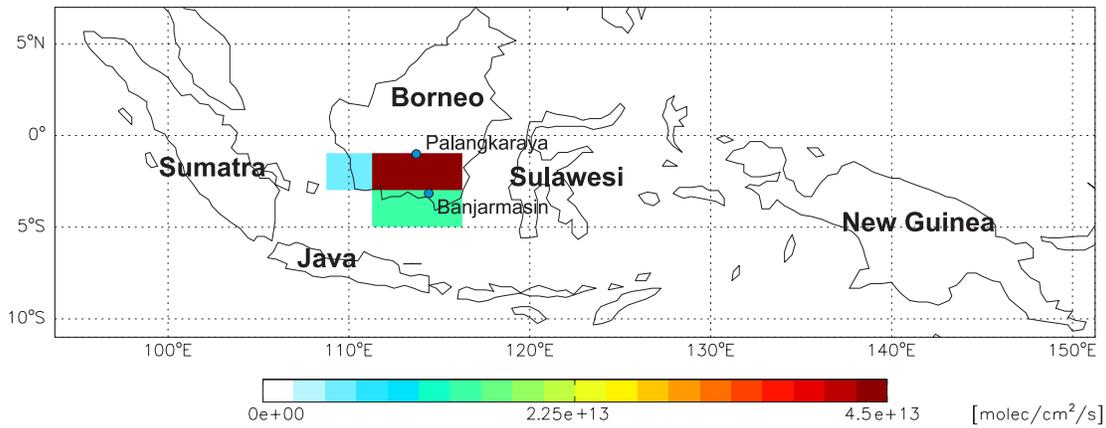

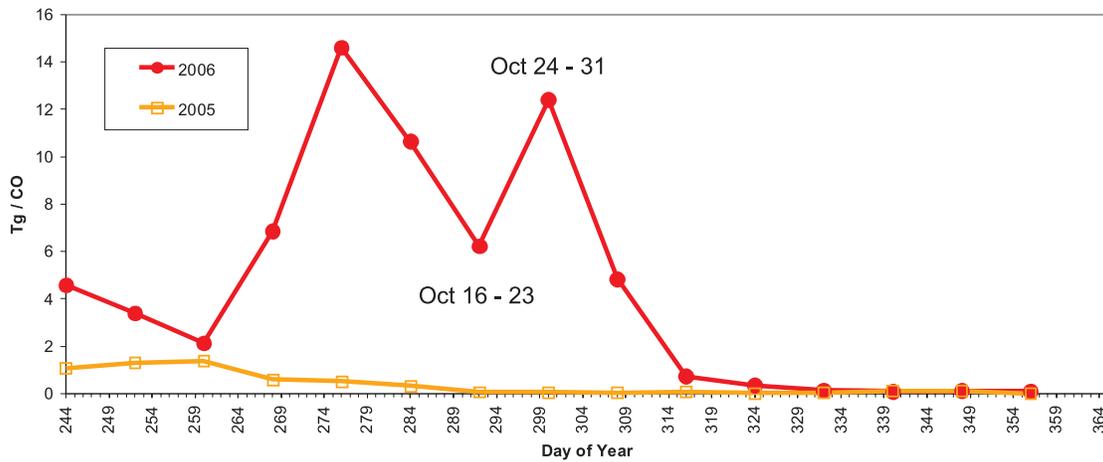

Figure 6: The time evolution of TES and the GEOS-Chem *Base* run for CO, O<sub>3</sub> and H<sub>2</sub>O in late 2005 and 2006. GFED CO emissions are shown corresponding to the axis on the right. The GEOS-Chem *2006e05* and *3xE* runs are also shown. All values are half-month means plotted at 0.25 and 0.75 of each month and the TES averaging kernel has been applied to the model data.

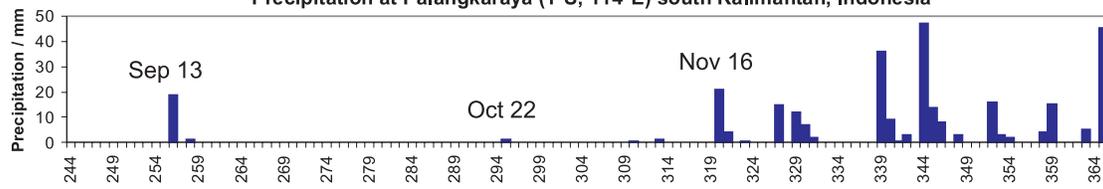

### GFEDv2 CO emissions 2006 November 1-15

### GFEDv2 CO Emissions from Indonesia

### Precipitation at Palangkaraya (1°S, 114°E) south Kalimantan, Indonesia

### Precipitation at Banjarmasin (3.43°S, 114.75°E) south Kalimantan, Indonesia

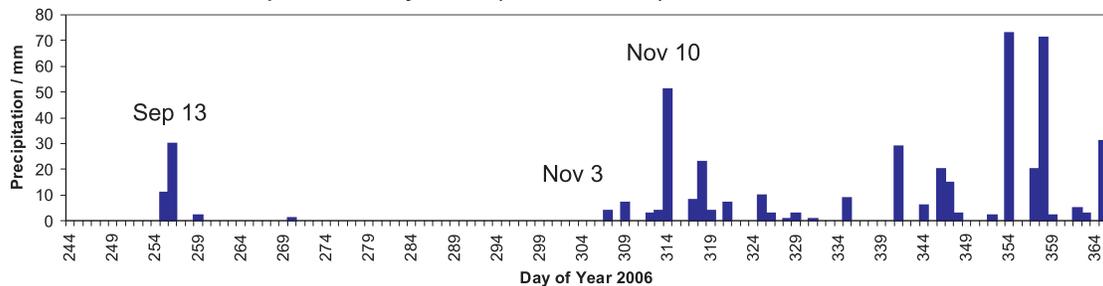

Figure 7: GFED CO emissions ( $2^\circ \times 2.5^\circ$  resolution) originating from the region of Indonesia and New Guinea (top panel). Regional CO emissions from 2005 and 2006 plotted on the 4<sup>th</sup> day of each 8-day interval (2<sup>nd</sup> panel). Precipitation at Palangkaraya and Banjarmasin in late 2006 (from <http://www.tutiempo.net>, lower panels).

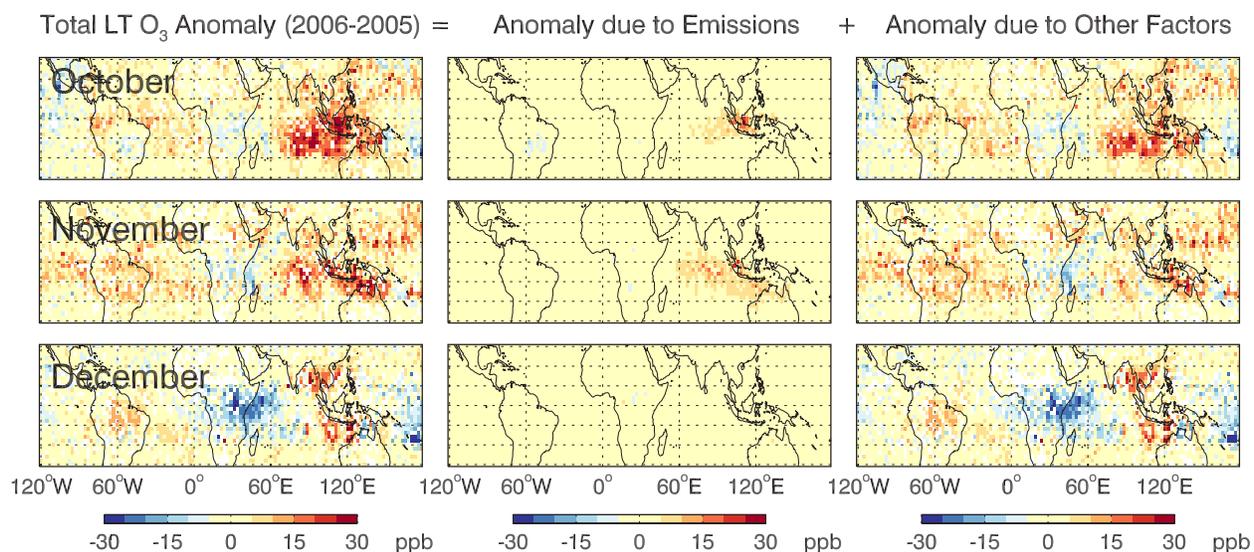

Figure 8: Separating the effects of emissions and meteorology. The left column shows the total monthly 2006-2005 anomalies for the LT calculated from the *3xE* GEOS-Chem run (increased biomass burning emissions in November 2006) and the *Base* run for 2005. The middle column shows the contribution directly from the *3xE* biomass burning enhancement in 2006 relative to 2005 biomass burning emissions ( $2006\ 3xE - 2006e05$ ). The right column shows the contribution to the anomaly from other factors ( $2006e05 - 2005\ Base$ , which is also the difference of the other two columns) and is equivalent to the right column in Figure 4.

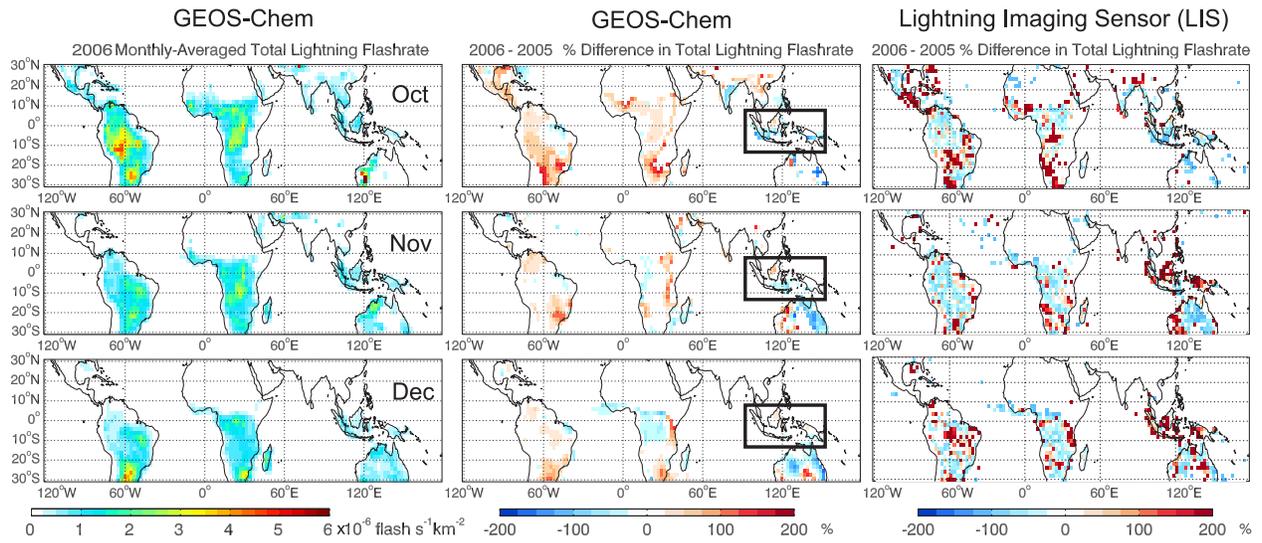

Figure 9: GEOS-Chem 2006 lightning flash rate (left), GEOS-Chem 2006-2005 lightning anomalies (middle), and Lightning Imaging Sensor (LIS) lightning anomalies (right) both in percent. The rectangle shows the region (9°N-13°S and 93.75-151.25°E) for which model lightning is too low necessitating an increase.

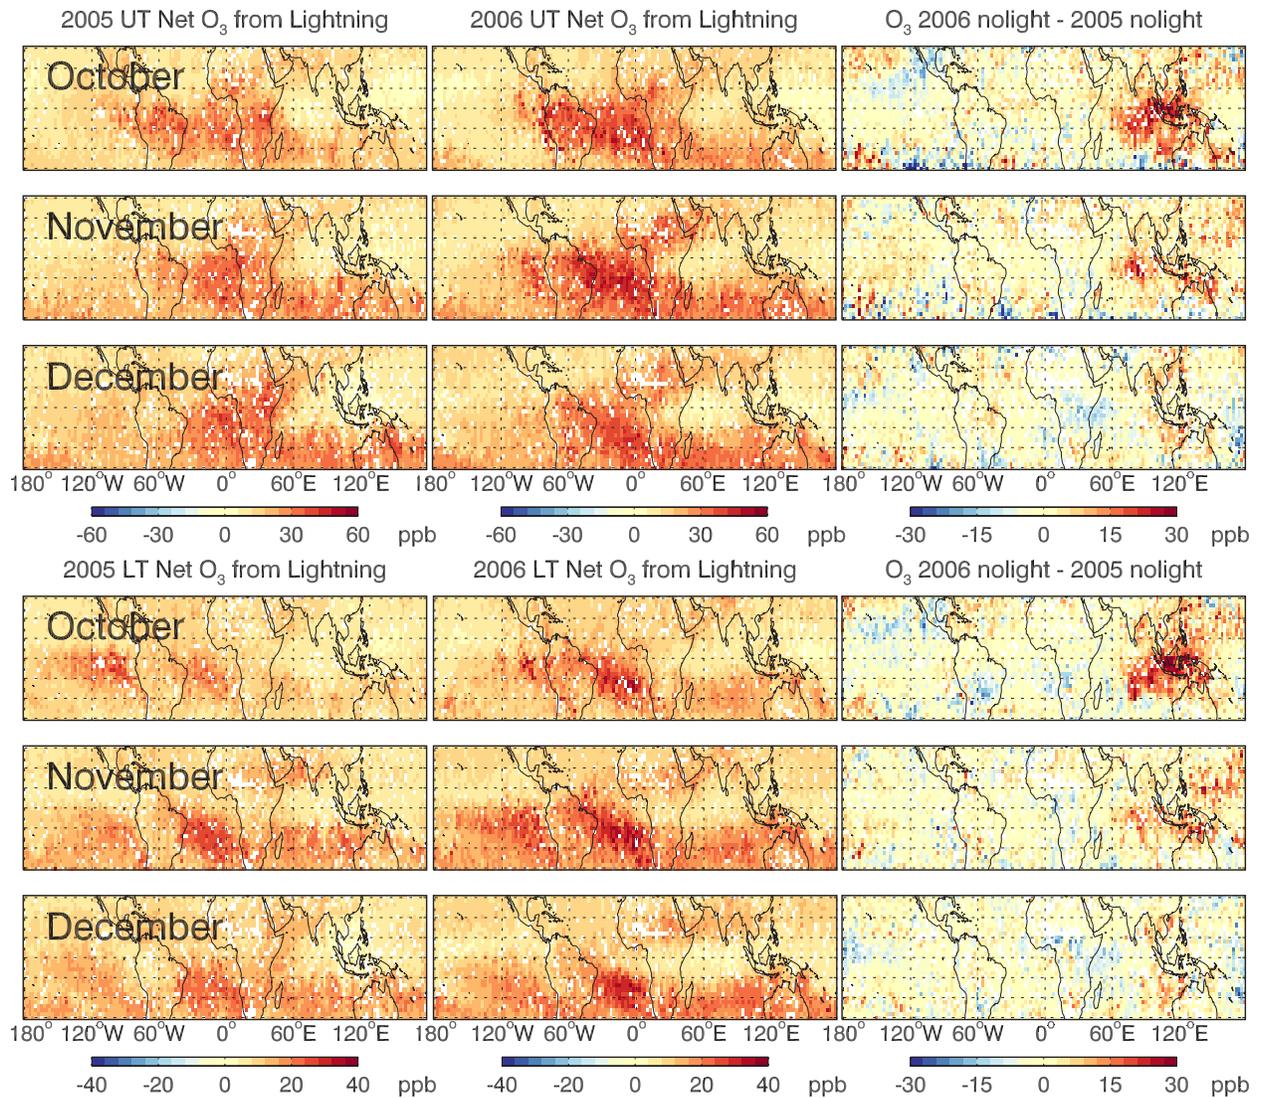

Figure 10: Net O<sub>3</sub> from lightning in the UT and LT for October-December determined by taking the difference between ozone in *Base-13* minus *NoLight* for 2005 (left) and 2006 (middle). The 2006-2005 difference between the *NoLight* runs (right) shows a strong resemblance to the overall ozone anomaly in Figure 3.

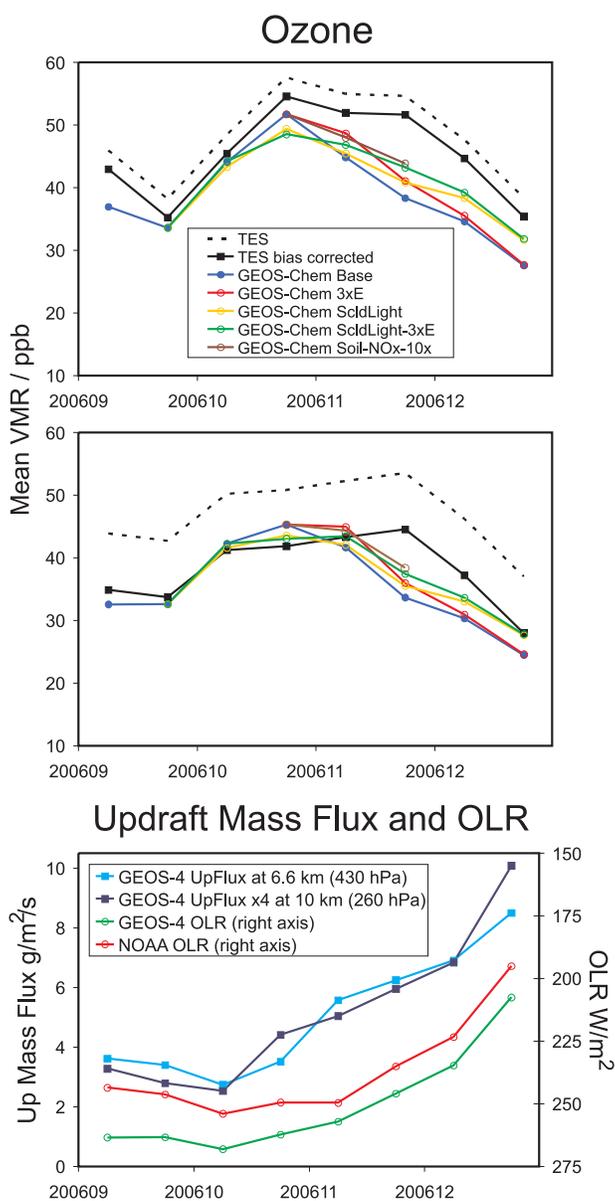

Figure 11: Time evolution of  $O_3$  from TES and the GEOS-Chem *Base*, *3xE*, *ScldLight*, *ScldLight-3xE* and *SoilNO<sub>x</sub>10* runs for the UT and LT (upper and middle panels). The TES averaging kernel has been applied to the model data. GEOS-4 updraft mass fluxes for model sigma levels near 10 km (multiplied by 4) and 6.6 km are also shown with GEOS-4 and NOAA Outgoing Longwave Radiation (OLR) (bottom panel). The GEOS-4 data correspond to the same region (11°S-5°N, 91.25-121.25°E) as the TES and GEOS-Chem data, but the NOAA OLR averages are for a slightly different region (11.25°S-6.25°N, 91.25-121.25°E) due to its different grid. All values are half-month means plotted at 0.25 and 0.75 of each month.

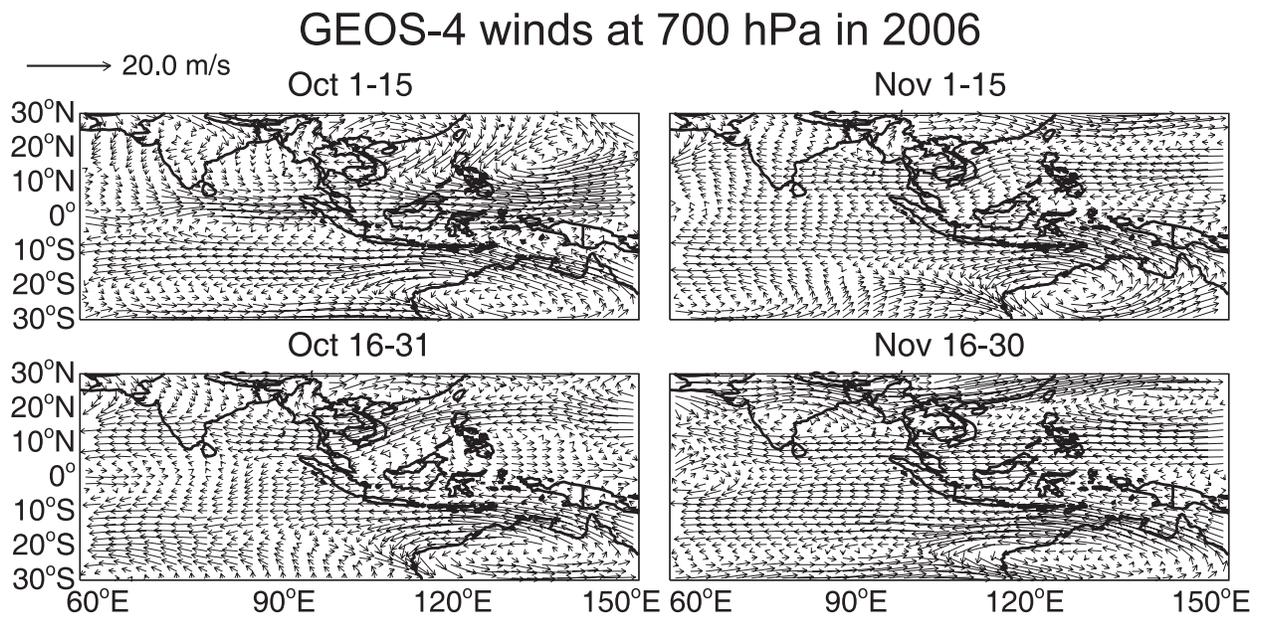

Figure 12: GEOS-4 horizontal winds at 700 hPa for half-month intervals in 2006.

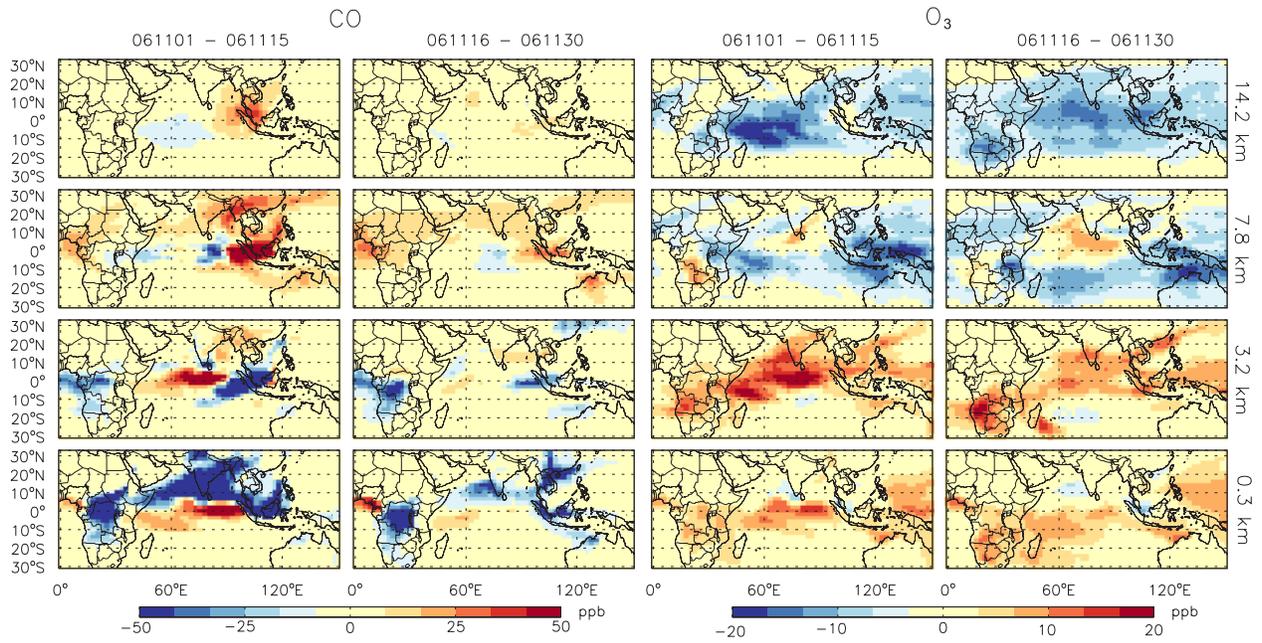

Figure 13: CO and O<sub>3</sub> contributions from convection in GEOS-Chem, determined as the *Base* run minus *NoConvection* run. Panels show model levels near the base of the tropopause (top row), in the UT (second row), LT (third row) and boundary layer (bottom row) for the first and second halves of November 2006. Approximate altitudes corresponding to GEOS-4 sigma levels are given on the right.

# Outgoing Longwave Radiation (OLR) 2006-2005

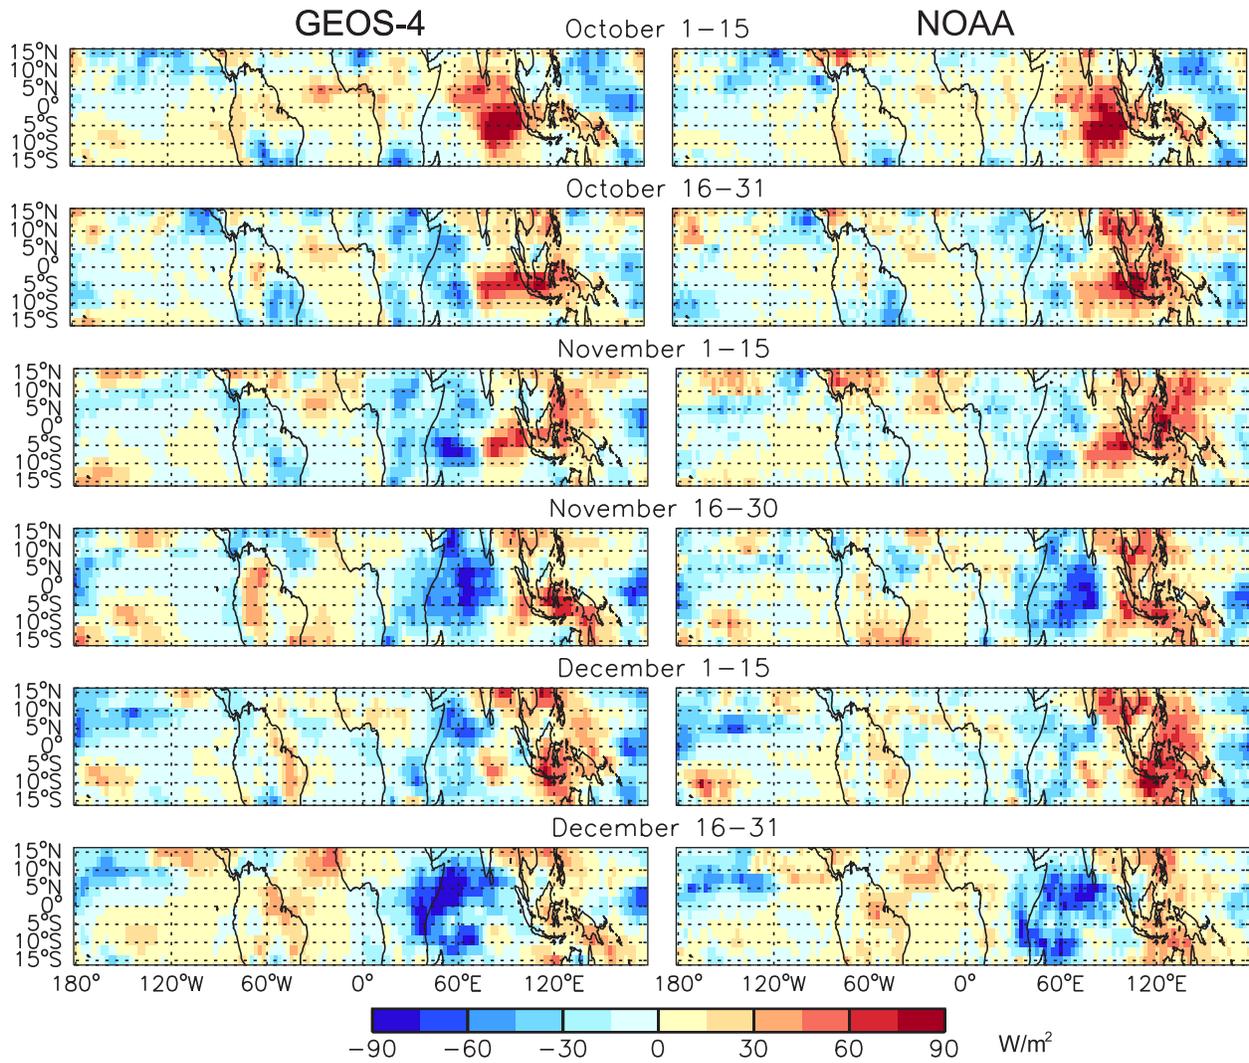

Figure 14: Differences in OLR (2006-2005) from GEOS-4 and NOAA for October to December in half-month intervals.

# GEOS-4 - NOAA 2006 Outgoing Longwave Radiation (OLR)

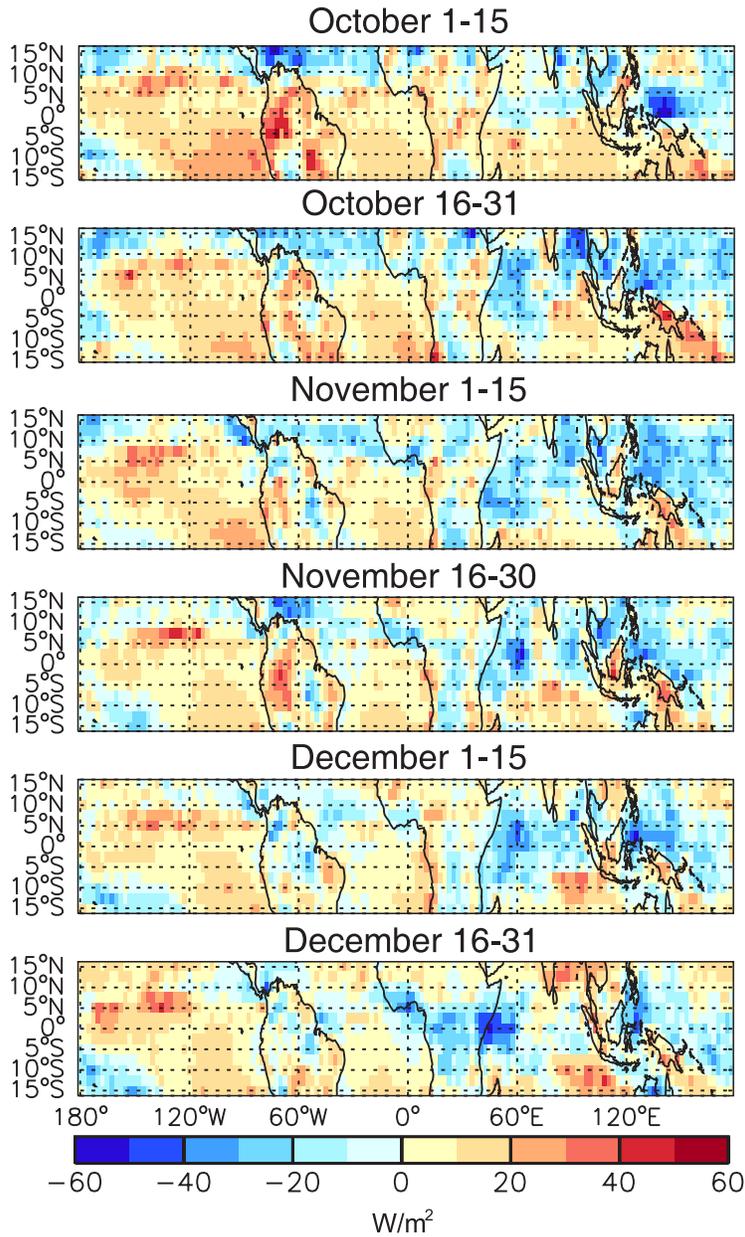

Figure 15: GEOS-4 – NOAA OLR for October to December 2006 after applying a bias correction of  $13 W/m^2$  to account for differences between the OLR datasets (see Figure 11).

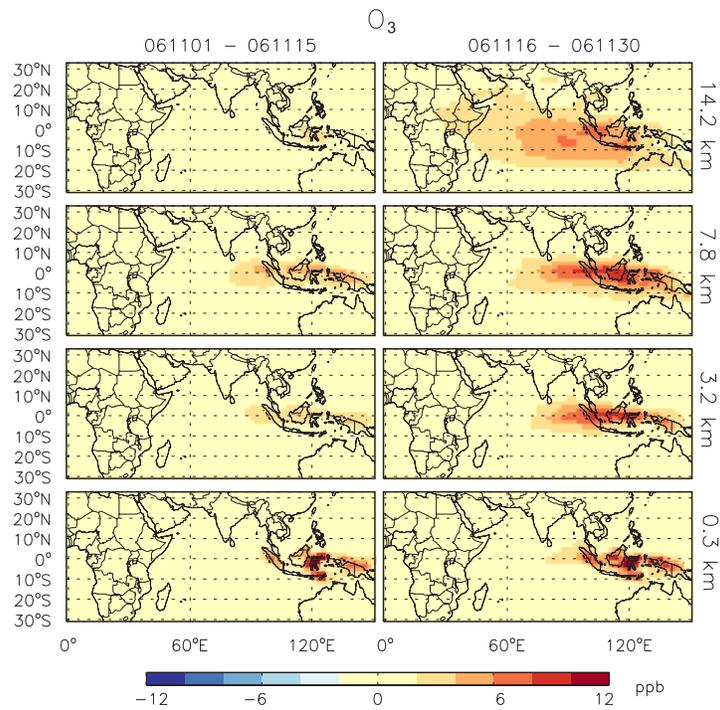

Figure 16: Ozone change resulting from an increase in soil  $NO_x$  emissions by a factor of 10, for the first and second halves of November near the base of the tropopause, UT, LT and BL. The change was calculated from the difference of *SoilNOx10 - Base*. Approximate altitudes corresponding to GEOS-4 sigma levels are given on the right.
